The list of diseases, syndromes, and inflammatory processes associated with peripheral blood (>450-500 eosinophils/mm^3) or tissue eosinophilia, or both, is quite extensive (see Table 70-1). Of course, the most common causes are infections with parasitic helminths and allergic diseases and their related inflammatory reactions. Effective clinical assessment of patients with eosinophilia requires taking a careful and detailed history, including travel information (e.g., where the patient has lived; drug use, including intravenous drugs, L-tryptophan, vitamin supplements, and other over-the-counter medications; diet; allergic symptomatology).[8] Hypoadrenalism is associated with eosinophilia because of the reduced levels of glucocorticoids. In addition, the systemic nature of many of the nonallergic/noninfectious conditions involving eosinophilia dictates that a careful history of fever, weight loss, myalgias, arthralgias, arthritis, rashes, and lymphadenopathy be obtained as well. Symptomatic or asymptomatic eosinophilia in patients taking drugs associated with known eosinophil-related drug reactions strongly dictates that their use be discontinued, in which case follow-up evaluation should be done to confirm that the eosinophilia and related symptoms have resolved. Patients with eosinophilia who have resided in or visited areas endemic for helminths or other parasites should be examined for intestinal and blood-borne infections, with additional serologic evaluation as necessary to identify the causative agent. It is important to be aware that the degree of eosinophilia associated with parasitic infections is determined by the development, migration, and distribution of the specific parasite and the host's immune response. Eosinophilia is most pronounced in infections such as trichinosis, strongyloides, ascaris, schistosomiasis, filariasis, and gnathostmiasis, which have a phase that involves migration through tissues. Once the more common and obvious causes of eosinophilia have been excluded, the differential diagnosis of eosinophilia becomes more difficult because of the complexity and number of potential organ systems and conditions involved (see Table 70-1).

Monitoring of Eosinophil Activity

Monitoring of eosinophil activity in situ has become more routine. Reasons for this include an increased appreciation for the importance of the greater numbers of tissue eosinophils compared with the number in circulating and their activated status, due to cytokine exposure in the tissue microenvironment. Tissue biopsies have become more routinely used for the clinical evaluation of eosinophil function in diseases involving the skin, lungs, lymph nodes, heart, and other tissues. The difficulties inherent in accurately determining the numbers of eosinophils make routine clinical evaluation of tissue eosinophils somewhat impractical. Alternative approaches such as analysis of tissue secretions from affected organs (e.g., bronchoalveolar lavage of the lung) have been used with success in evaluating eosinophil function in asthma. In addition to the more routine histochemical identification and enumeration of eosinophils and the immunochemical localization of secreted eosinophil granule cationic proteins in tissue biopsies, two other methods have been extensively used to monitor eosinophil activation, secretion, and involvement in disease pathogenesis: (1) the identification of activated eosinophils by staining with a monoclonal anti-ECP antibody EG2 that recognizes a secreted, deglycosylated form of the protein and (2) measurement of the eosinophil granule cationic proteins such as MBP, ECP, and EDN by radioimmunoassay or enzyme-linked immunosorbent assay (ELISA) in various body fluids including serum, plasma, urine, sputum, nasal lavage, and BAL fluid. Under controlled sampling conditions, measurements of these eosinophil granule products have served as excellent biomarkers of eosinophil secretory activity in vivo and eosinophil involvement in a variety of allergic, parasitic, and certain inflammatory and skin diseases not normally associated with blood or tissue eosinophilia. Examples include assays of MBP and ECP in bronchoalveolar lavage and nasal lavage in asthma and allergic rhinitis, in serum and plasma in lymphatic filariasis, and in skin diseases such as chronic idiopathic urticaria. Such measurements likely reflect in vivo secretion in tissues and/or secretory activity of eosinophils in the fluid sampled and have provided compelling evidence for relationships between eosinophil secretory activity and disease severity.

PATHOGENESIS OF EOSINOPHIL-ASSOCIATED END-ORGAN DAMAGE IN HYPEREOSINOPHILIC SYNDROME

Sustained eosinophilia, regardless of origin (whether reactive, clonal, or idiopathic), has the capacity to lead to end-organ damage. The multiple manifestations of such eosinophil-associated end-organ damage are considerable (Table 70-2). However, not all cases of sustained hypereosinophilia necessarily lead to end-organ damage. For example, patients with syndromes such as eosinophilic pneumonia and episodic angioedema with eosinophilia characteristically fail to develop the cardiac damage characteristic of HES patients. Experimentally, IL-5 transgenic mice, which develop extremely high numbers of peripheral blood eosinophils, do not develop significant end-organ damage, suggesting that other factors in addition to IL-5 are likely necessary for eosinophil tissue damage. Because of rather limited experience, it is not currently known whether true myeloproliferative eosinophilic disorders of clonal origin have the capacity to

lead to end-organ damage. Of note, HES patients in the National Institutes of Health (NIH) series who ultimately developed cardiac disease exhibited features suggestive of a diagnosis of a myeloproliferative neoplasm, including splenomegaly, thrombocytopenia, anemia, elevated B_{12} levels, cytogenetic abnormalities, and circulating myeloid precursors and myeloid dysplasia. As noted earlier, eosinophils express a number of granule cationic protein mediators capable of inducing thrombotic events, endothelial and endocardial damage, and neurotoxicity (the ribonucleases EDN and ECP). Eosinophil granule MBP and ECP are potent cellular toxins capable of damaging normal host cells and tissues in a manner reminiscent of end-organ damage associated with tissue eosinophilia. In addition, the eosinophil has the capacity to undergo a potent respiratory burst on activation, generating reactive oxidative species that can directly, or in association with eosinophil peroxidase, induce oxidant-mediated tissue damage. However, the mechanisms by which eosinophils induce thrombosis and thromboembolic events associated with hypereosinophilic diseases remain unclear, especially because consistent systemic alterations in coagulation and fibrinolytic pathways in these patients have not been identified. The eosinophil granule cationic proteins do, however, appear to have the capacity to alter thrombomodulin activity, suggesting one possible mechanism for thromboembolism in hypereosinophilic heart disease.[9]

HYPEREOSINOPHILIC SYNDROME

Hypereosinophilic syndrome (HES) is a group of disorders that are marked by a sustained overproduction of eosinophils.[10] The cause of HES can be attributed to several well-defined entities. Approximately 10% to 15% of patients with HES do not have a myeloid malignancy but rather an abnormal clonal $CD3^{-}CD4^{+}$ T-cell population that has been shown to produce interleukin-5 (IL-5) in vitro. This variant is referred to as *lymphocytic variant hypereosinophilia.* Furthermore, a small number of patients with a clinical picture of HES have been shown to have myeloid malignancies associated with mutations involving platelet-derived growth factor receptor (PDGFRA or PDGFRB) or the fibroblast growth factor receptor (FGFR). These disorders are categorized by the World Health Organization (WHO) as myeloid and lymphoid malignancies associated with eosinophilia and genetic abnormalities. Those patients with HES in whom a specific etiology cannot be identified are classified as having idiopathic eosinophilia. Some of these IE patients have end-organ damage associated with their eosinophilia and suffer from the clinical syndrome of HES.

HES is characterized by a predilection for end-organ damage, most commonly involving the heart, with the development of eosinophilic endomyocardial fibrosis and related cardiac pathology. The currently defined criteria for HES (Table 70-3) include (a) persistent eosinophilia of greater than 1500 eosinophils/mm^3 for more than 6 months; (b) exclusion of other potential etiologies for the eosinophilia, including parasitic, allergic, or other causes; and (c) signs and symptoms of organ system dysfunction or involvement that appear related to the eosinophilia or are of unknown cause in the clinical presentation. Total leukocyte counts are often less than 25,000/mm^3 with 30% to 70% eosinophils. However, extremely high leukocyte counts (>90,000/mm^3) may be associated with a poor prognosis in some patients. These three primary features of the syndrome, including sustained eosinophilia of unknown etiology or disease association, along with evidence of organ involvement (see Table 70-3), are the defining characteristics of HES. The clinical manifestations of HES, as well as their frequency at presentation, are summarized in Table 70-2. The most commonly encountered features in approximately 50% to 75% of patients include the cardiovascular manifestations, especially endomyocardial disease and its associated thromboembolic complications, the major causes of morbidity (and mortality) in HES.

Table 70-3 Criteria for the Diagnosis of the Idiopathic Hypereosinophilic Syndrome

Eosinophils >1500/mm^3 for at least 6 months
Reactive causes of eosinophilia excluded
Known eosinophilic disease entities excluded
Evidence of eosinophilic end-organ damage
Clonal eosinophilic disorders excluded
FACTORS FAVORING A DIAGNOSIS OF HES
Elevated serum immunoglobulins
Elevated levels of tumor necrosis factor or interleukins (IL-5)
Elevated serum IgE levels
Good therapeutic response to corticosteroids

Differential Diagnosis of Hypereosinophilic Syndrome

As shown in Table 70-1, a large number of diseases have been identified that are associated with reactive, secondary eosinophilia and hypereosinophilia. Their clinical presentations vary significantly and must be clearly distinguished from HES. In particular, a number of eosinophilic diseases and syndromes of questionable or unknown etiology must be differentiated from HES, according to clinical and pathologic parameters. A number of these eosinophilic syndromes have pathologies that are generally restricted to specific organs (e.g., eosinophilic gastroenteritis and eosinophilic pneumonia) and lack the multiplicity of end-organ damage generally seen in HES. In disorders such as eosinophilic gastroenteritis, eosinophilic esophagitis, and eosinophilic cystitis, localized tissue eosinophilia may not be accompanied by eosinophilia in the peripheral blood. For reasons that remain unclear, these syndromes lack the propensity to develop toward secondary eosinophil-mediated cardiac disease. The major eosinophil-associated vasculitis is Churg-Strauss syndrome, which is characterized by a history of blood eosinophilia greater than 10%, asthma, pulmonary infiltrates (nonfixed), abnormalities in the paranasal sinuses, gastrointestinal and cardiac manifestations, mononeuropathy or polyneuropathy, extravascular eosinophilic infiltrates in blood vessels, renal insufficiency, and proteinuria.[11] Necrotizing vasculitis of small arteries and veins and extravascular granulomas are characteristic findings in biopsies from most, but not all Churg-Strauss patients. Asthma, peak eosinophil counts of greater than 1500/mm^3, and systemic vasculitis involving two or more extrapulmonary organs are the identifying characteristics of these patients. Although neurologic, pulmonary, and possibly paranasal findings may accompany HES, asthma is characteristically absent. Nevertheless, it may be difficult to make a clear-cut distinction between HES and Churg-Strauss syndrome in some patients, especially since responses to high-dose corticosteroids would be identical for both at the outset. T cells are critical in the development of Churg-Strauss syndrome and are thought to secrete increased levels of IL-5, IL-4, and IL-13, which promote mobilization and activation of eosinophils. Inhaled allergens, infections, vaccinations, drugs, and the use of leukotriene receptor antagonist therapy for asthma have each been associated with the development of Churg-Strauss syndrome. Autoantibodies to antineutrophil cytoplasmic antigens are detectable in 30% to 40% of cases, which suggests a role for B cells in its pathogenesis, leading to the use of rituximab as a therapeutic agent.

Eosinophilic syndromes with cutaneous involvement can generally be distinguished from HES by the histopathology of biopsied skin lesions. These syndromes include Kimura disease (angiolymphoid hyperplasia with eosinophilia), Wells syndrome (eosinophilic cellulitis), eosinophilic fasciitis, and eosinophilic pustular folliculitis. The syndrome of episodic angioedema with eosinophilia, characterized by a clinical course of periodic recurring episodes of angioedema, urticaria, fever, and marked blood eosinophilia, is not associated with end-organ cardiac damage and has thus been distinguished from HES. The eosinophil myalgia syndrome, induced by ingestion of

"tainted" L-tryptophan, is relegated to mainly historic interest, since there have not been any new cases following removal of the tainted L-tryptophan from the market.

A differential diagnosis of HES requires the exclusion of all identifiable eosinophilias of reactive, secondary etiologies (see Table 70-1). These especially include eosinophilias due to parasitic infections caused predominantly by helminthic parasites, but also by two enteric protozoans, *Dientamoeba fragilis* and *Isospora belli.* In adults, filarial infections and strongyloidiasis are most likely to elicit pronounced and prolonged eosinophilias, in contrast to *Trichinella spiralis* infections, which cause an acute eosinophilia that does not persist without reinfection. Infections with *Strongyloides stercoralis,* which have the capacity to induce marked hypereosinophilia that mimics HES, are particularly important to exclude, especially because HES has been misdiagnosed in patients with unsuspected strongyloidiasis, and treatment of these patients with immunosuppressive glucocorticoids can lead to disseminated, often fatal disease. Serial stool examinations and, in particular, assays for *Strongyloides* infection should be performed (e.g., strongyloides agar plate culture) since serologic ELISA assays may cross-react with other helminth infections such as filariasis, ascaris lumbricoides, and schistosomiasis. Parasitic helminth infections not amenable to or detectable by routine stool examinations, including tissue or blood-dwelling helminths causing filariasis, trichinosis, or visceral larval migrans (*Toxocara canis* infections in children), should be evaluated by diagnostic examinations of blood, tissue biopsies, or specific serologic tests (ELISAs) that are currently available.

CLINICAL MANIFESTATIONS OF HES

Hematologic Findings

The definitive hematologic manifestation of HES is sustained eosinophilia of 30% to 70%, with total leukocyte counts ranging from 10,000/mm^3 to 30,000/mm^3 (Fig. 70-4). However, extremely high leukocyte counts of greater than 90,000/mm^3 are not uncommon in some patients with HES, although they are often associated with a poorer prognosis. Blood smears from patients with HES generally show more or less normal, mature eosinophil morphology, including typical bilobed nuclei and granule-rich cytoplasm. However, eosinophilic myeloid precursors may also be noted, though less commonly, and eosinophils may also exhibit morphologic abnormalities including nuclear hypersegmentation, decreased size and/or numbers of secondary granules, and cytoplasmic vacuolization. The presence of myeloblasts and/or dysplastic findings in the peripheral blood may suggest an alternative, clonal etiology such as AML or a myelodysplastic syndrome. Ultrastructurally, HES eosinophils may show a selective loss of secondary granule components (crystalloid MBP-containing core or granular matrix, or both), decreased numbers and/or size of granules, and increased numbers of cytoplasmic lipid bodies and tubulovesicular structures that may be involved in eosinophil secretion of secondary granule contents during the process of piecemeal degranulation.

In addition to the hypereosinophilia, patients with HES may also present with an absolute neutrophilia, further contributing to their overall increased leukocyte counts. This may include band forms, less mature precursors, and alterations in neutrophil nuclear segmentation and cytoplasmic granules. Basophilia, when seen in some HES patients, is usually minimal. Levels of leukocyte alkaline phosphatase may be abnormally elevated or decreased in HES patients, and serum vitamin B_{12} and B_{12}-binding proteins can be normal or elevated. Platelet counts are decreased or increased in 31% and 16% of patients, respectively. Approximately 50% of HES patients may be anemic, with nucleated erythrocytes being present in the peripheral blood. The bone marrow in these patients is hypercellular with significant increases in the percentage of eosinophils (generally from 25% to 75% of marrow elements) and a clear left shift in eosinophil maturation. Myeloblasts are generally normal in number, and marrow fibrosis is rare. Splenomegaly has been reported in approximately 43% of HES patients (see Table 70-2). Hypersplenism in these individuals may contribute to the development of both thrombocytopenia and anemia. Splenic pain induced by capsular distention or infarction is a frequent complication of splenic involvement. The progressive leukocytosis with hypereosinophilia in these patients, along with the hypercellular bone marrow and lack of increased numbers of myeloblasts, can make it difficult to distinguish HES from other myeloproliferative neoplasms.

Cardiovascular Findings

Cardiac manifestations occur in approximately 50% to 60% of patients and are a major cause of morbidity with an associated 5-year mortality of 30% (Table 70-4; also see Table 70-2). Prior to the advent of early diagnosis, improved management, and newer therapies, cardiac disease was the leading cause of morbidity and mortality in HES patients. The cardiac and thromboembolic manifestations of HES are likely eosinophil-mediated. However, the risks for developing cardiac disease are not necessarily related to the extent or duration of the eosinophilia, as patients who ultimately develop cardiac involvement are more likely to be males with an HLA-Bw44

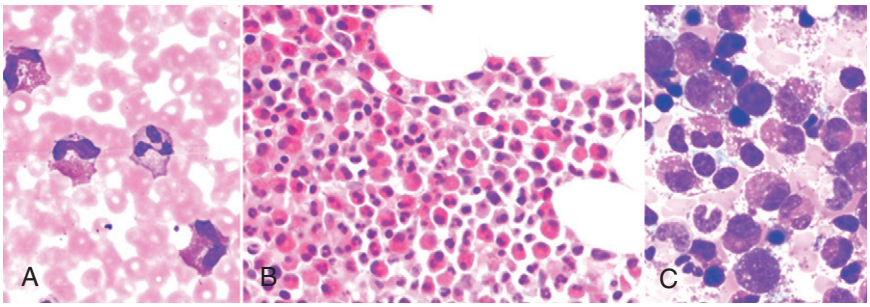

Figure 70-4 HYPEREOSINOPHILIC SYNDROME. This illustration is from the case of a 38-year-old woman who was found to have a marked eosinophilia when she presented with headaches, nausea, and vomiting. Her WBC was 16,900/μL, with 36% eosinophils (**A**). Her bone marrow was hypercellular and showed sheets of eosinophils (**B**). On the aspirated material (**C**), eosinophils and eosinophilic precursors accounted for more than 70% of the cells. The patient had no obvious infectious process and no allergies. There was no malignancy associated with eosinophilia such as T-cell lymphoma, Hodgkin lymphoma, or other myeloid disease. Peripheral blood lymphocyte phenotyping showed no abnormal T-cell subset. Cytogenetic analysis showed a normal female karyocyte, and FISH analysis for del 4q12 showed no deletion of CHIC2.

phenotype, develop splenomegaly and thrombocytopenia, have elevated vitamin B_{12} levels, and have abnormal hypogranular and vacuolated blood eosinophils and circulating early myeloid progenitors. In contrast, those HES patients who do not develop heart disease tend to be females with angioedema, hypergammaglobulinemia, and increased serum IgE levels and immune complexes. The cardiac damage seen in HES, progressing from early necrotic changes through thrombosis and fibrosis, is identical to that seen in patients with hypereosinophilias of diverse etiologies, including tropical eosinophilias caused by loiasis; filarial infections; parasitic infections such as trichinosis and visceral larval migrans, drug reactions or administration of GM-CSF; eosinophil leukemia; eosinophilia due to various solid tumors or lymphomas; and Churg-Strauss syndrome. Because identical forms of cardiac pathology can develop in patients with hypereosinophilias of diverse etiologies, and because some patients never go on to develop cardiac involvement, the pathogenesis of eosinophil-associated cardiac disease likely involves eosinophils and as-yet-undefined factors required for the recruitment, activation, and secretion of eosinophilic constituents in the heart and associated cardiovascular tissues.

The pathology of eosinophilic endomyocardial fibrosis is similar to that of tropical endomyocardial fibrosis, except for the frequent absence of eosinophilia in the latter disorder. However, the general absence of hypereosinophilia in patients with tropical endomyocardial fibrosis is thought to be a function of the late stage of helminthic disease in which the heart disease develops. The histopathology of cardiac involvement in HES is well characterized and can evolve through three sequentially defined stages for which eosinophils and secretion of eosinophil-derived mediators may be directly involved. These include (a) an initial acute necrotic stage of short duration (5 weeks) involving active endomyocarditis, (b) a later thrombotic stage (10 months) with mural thrombus formation over endocardial lesions, and (c) a late fibrotic stage (after approximately 2 years of illness) with development of endomyocardial fibrosis. The early necrotic stage with damage to the endocardium involves marked eosinophil and lymphocyte infiltration of the myocardium with myocardial necrosis, formation of eosinophilic microabscesses, and eosinophil degranulation. However, this early necrotic stage of cardiac disease is usually not recognized clinically. Echocardiography and angiography may fail to detect abnormalities at this early stage of the disease because ventricular thickening has not yet occurred and endomyocardial biopsies, generally from the right ventricle, are required to make the diagnosis of cardiac involvement. Treatment of HES patients with corticosteroids during this acute necrotic stage may avert or control the subsequent development of myocardial fibrosis. However, patients often present at the later stages of the cardiac involvement. In the second stage, thrombi form over the damaged endocardium in either of the ventricles or the atrium, generally with sparing of the aortic and pulmonary valves. Progressive scarring at sites of mural thrombus formation ultimately leads to the late fibrotic stage, with endomyocardial fibrosis resulting in a restrictive cardiomyopathy and mitral or tricuspid valve regurgitation, or both. The more common clinical manifestations in the later progressive stages of endomyocardial fibrosis include dyspnea, chest pain, signs of left or right ventricular congestive heart failure, or both, murmurs from mitral valve regurgitation, cardiomegaly, and T-wave inversions. Most patients who progress to this stage of HES cardiomyopathy will benefit from standard medical therapies for congestive heart failure or, where hemodynamically indicated, mitral valve replacement. Two-dimensional echocardiography is a sensitive method for detecting cardiac abnormalities in these patients, with visualization of mural thrombi and the various manifestations of fibrosis, including thickening of the mitral valve and its supporting structures. Approximately 80% of HES patients have echocardiographic abnormalities, with thickening of the left ventricular free wall the most common finding (68% of patients). Cardiac catheterization may also be useful for demonstrating elevated right and left ventricular end diastolic pressures, and angiography may be used to visualize valvular incompetence. Although electrocardiographic changes in these patients are common, they are not specific to HES. Recently, intractable coronary artery spasm has been reported as the sole cardiovascular manifestation of HES. Cardiac magnetic resonance imaging with late enhancement with gadolinium may be helpful in detecting myocardial fibrosis and signs of inflammation as well as being of use in monitoring the patient's clinical course. Although each of these imaging procedures may be useful diagnostically or in following the clinical course of an individual patient, endomyocardial biopsy from the right or left ventricle remains the gold standard diagnostic procedure.

Histopathologic evaluation of the heart of HES patients generally shows four dominant features: (a) endocardial fibrosis and thickening, including involvement of mitral valve and supporting structures; (b) mural thrombus and granulation tissue on the endocardium with extensive infiltration by eosinophils; (c) thrombotic and fibrotic involvement of small intramural coronary vessels, including inflammatory cells and eosinophils; and (d) eosinophilic infiltration of the endocardium and, in some cases, of the myocardium. In a multicenter study of biopsy and postmortem specimens of cardiac tissue from HES patients at various stages of eosinophilic endomyocardial disease, activated eosinophils (identified by staining with the EG2 anti-ECP monoclonal antibody) and marked intracardiac extracellular deposition of eosinophil granule cationic proteins were identified mainly in areas of acute tissue damage on and beneath the endocardium in areas of myocardial necrosis, and in the walls of small vessels. The presence of activated eosinophils and toxic granule proteins in the lesions early in this disease suggests an active role for eosinophils and their products in inducing endocardial damage and myofibrillar injury, although the mechanisms involved in eosinophil recruitment into the heart have yet to be identified. In vitro studies have shown that secretion products of activated eosinophils can damage heart cell plasma membranes in rats. In addition, eosinophil peroxidase in the presence of hydrogen peroxide and bromide or thiocyanate ion can damage the endothelium of an isolated rat heart, and eosinophil granule proteins can impair thrombomodulin activity, findings that support a role for these eosinophil products in the development of endocardial injury and subsequent thrombotic events in HES. The in vitro findings that eosinophil secretion products such as EDN can induce fibroblast proliferation, that ECP alters fibroblast proteoglycan synthesis, and

that MBP can augment IL-1 or TGF-β–induced production of inflammatory cytokines (IL-6 and IL-11) by fibroblasts, confirm that eosinophils play a pivotal role in the development of endocardial fibrosis in later stages of the disease. Treatment involves medical interventions to prevent heart failure as well as to prevent symptoms. Prophylactic anticoagulation is warranted to avoid thrombotic complications. Unless the patient has an FIP1L1-PDGFRA fusion gene in which imatinib is the therapy of choice, corticosteroids are the mainstay of therapy. Occasionally, surgical resection of ventricular masses or heart valve replacement is indicated.

Pulmonary Findings

Approximately 50% of HES patients have pulmonary involvement, with the most common symptom being a chronic and persistent (usually nonproductive) cough. Although the physiologic basis for pulmonary involvement in HES is not known, it may be secondary to congestive heart failure or numerous other factors, including infiltration and sequestration of eosinophils in lung tissues or pulmonary emboli originating from ventricular thrombi. Although bronchospasm has been noted in some patients, asthma is quite rare in HES. Transudative pleural effusions are the most common abnormality in patients with frank congestive heart failure. In contrast to chronic eosinophilic pneumonia, the pulmonary infiltrates seen in 14% to 28% of HES patients were either diffuse or focal, without any preference for particular regions of the lung. Pulmonary infiltrates in HES may or may not clear with prednisone treatment, and pulmonary fibrosis can develop in patients with endomyocardial fibrosis.

Neurologic Manifestations

As noted in Tables 70-2 and 70-4, neurologic involvement is quite common in HES (approximately 50% of patients), including three different types of manifestations. The first form of neurologic involvement is caused by thromboemboli, which may originate from intracardiac thrombi in the left ventricle. These thromboembolic episodes may occur even before overt cardiac disease is visible by echocardiography. Patients with thrombotic complications may experience embolic strokes or transient ischemic attacks that may be multiple and recurrent, and these episodes may occur even though the patient is adequately anticoagulated. The second type of neurologic manifestation involves primary diffuse central nervous system (CNS) dysfunction of unknown etiology. HES patients may variably exhibit changes in behavior, confusion, ataxia, and loss of memory. The third neurologic abnormality noted in HES is the development of peripheral neuropathy, which can occur in approximately 50% of HES patients exhibiting neurologic involvement. This includes symmetric or asymmetric sensory polyneuropathies, including sensory deficits, painful paresthesias, or mixed sensory and motor defects. These neuropathies may improve with steroid administration or other treatments, may be stable or continue to progress despite therapy, or may improve or resolve with time. The histopathology of the involved nerves usually shows varying degrees of axonal loss, without evidence of vasculitis or direct or peripheral eosinophil infiltration. The presence in eosinophils of two granule cationic proteins, EDN and eosinophil cationic protein, both equally potent in inducing a neurotoxic and paralytic syndrome known as the Gordon phenomenon when injected (intrathecally) into rabbits, has led to the hypothesis that these proteins might be responsible for inducing the various neuropathies commonly seen in HES. The histopathology of the cerebrocerebellar dysfunction in the brains of experimental rabbits undergoing the Gordon phenomenon includes a spongiform degeneration of white matter and loss of Purkinje cells, changes not comparable to the peripheral axonal nerve damage seen in HES. Both EDN and ECP (related, approximately 16-kDa cationic proteins with 70% amino acid sequence homology) are members of the ribonuclease gene family and possess potent ribonuclease activity and cellular toxicities in vitro. However, no direct evidence shows that these ribonucleases and cellular toxins have the capacity to mediate the types of neurologic damage seen in HES, nor have these proteins been visualized by immunochemical means at sites of HES neuropathology. Marked elevations in CSF levels of IL-5, MBP, and EDN have been documented in children with raccoon roundworm infections, progressive neurologic deterioration, and deep white matter changes on magnetic resonance images of the brain. Thus the pathogenesis of the encephalopathic, CNS, and peripheral manifestations of HES-associated neuropathy remains poorly defined.

Cutaneous Manifestations

The skin is frequently involved in HES pathology, with cutaneous manifestations present in greater than 50% of patients (see Table 70-2). The skin lesions associated with HES most commonly fall into three categories: (a) angioedematous and urticarial lesions; (b) erythematous, pruritic papules and nodules; and (c) mucosal ulcerations (see Table 70-4).[12] Patients with angioedema and urticaria are more likely to have a benign disease course that is responsive to corticosteroids, without the development of cardiac or neuropathic complications. A subgroup of HES patients with cyclical angioedema and eosinophilia are now considered to have a syndrome (episodic angioedema with eosinophilia) that is distinct from classic HES. These patients have a disorder with recurrent attacks of angioedema, urticaria, fever, and bodyweight gain that can be quite pronounced. These clinical manifestations are associated with marked leukocytosis and eosinophilia during the episodes. In HES patients who develop papular or nodular lesions (Fig. 70-5), the lesions usually improve

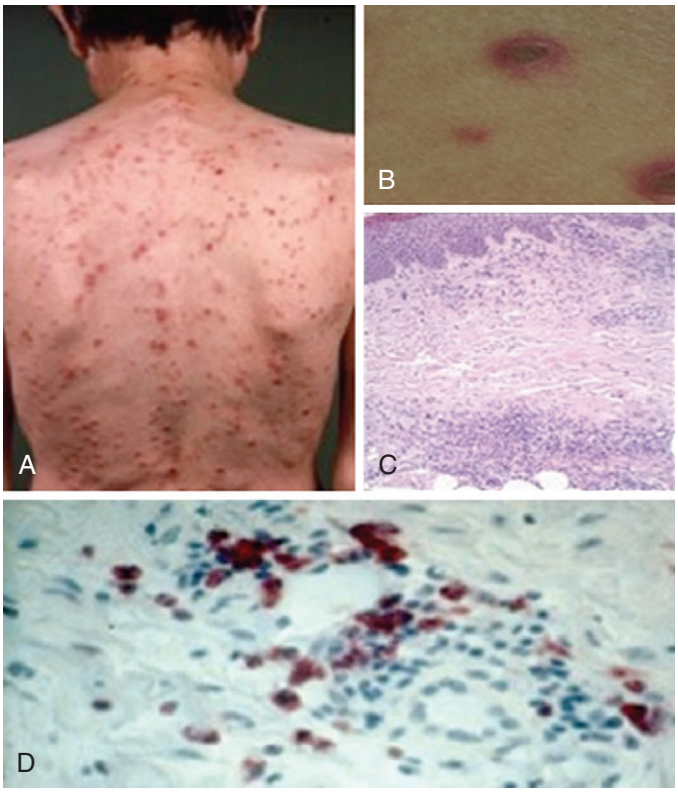

Figure 70-5 DERMATOLOGIC MANIFESTATIONS OF HES. Erythematous pruritic papules and nodules (**A**). Partially centrally ulcerated (**B**) hematoxylin-eosin-stained biopsy tissues demonstrating inflammatory cell infiltrates largely consisting of eosinophils and lymphocytes (**C**). Larger magnification of perivascular infiltrate with numerous eosinophils (**D**). *(From Plötz, S.G., Hüttig B, Aigner B, et al: Clinical overview of cutaneous features in hypereosinophilic syndrome.* Curr Allergy Asthma Rep *12:85, 2012.)*

concomitantly with positive responses to systemic therapy. Dermal biopsies in these patients generally show mixed cellular infiltrates, including eosinophils, without signs of vasculitis. Perivascular eosinophilic infiltrates are also found in these lesions. The aquagenic erythematous pruritic eruptions and indurated papules and nodules in some HES patients respond to psoralen and ultraviolet light A therapy (PUVA); in some cases, this treatment is accompanied by a return of eosinophil counts to normal. PUVA therapy may also be effective for the cutaneous manifestations of HES associated with HIV infection (exfoliative erythroderma, linear flagellate plaques). HES-associated pruritus and nodular lesions have also been controlled with Dapsone (75-150 mg/day) and prednisone therapy. Oral sodium cromoglycate (cromolyn sodium) given before meals has also been reported to be efficacious, though neither of these agents had any effect on peripheral eosinophilia. Severe and sometimes incapacitating mucocutaneous ulcerations may be a prodrome to HES and indicate a subset of HES patients with a poor prognosis. These lesions can appear at multiple sites, including the mouth, nose, pharynx, penis, esophagus, stomach, and anus; lesions can flare up independently of other clinical manifestations of HES. Biopsies of the ulcerative lesions usually show mixed cellular infiltrates, without a predominance of eosinophils or any evidence of vasculitis or microthrombi. These ulcers have generally been resistant to treatment with topical or systemic corticosteroids, colchicine, and hydroxyurea, but they have recently been shown to respond to IFN-α with complete and durable remissions.

Eosinophils are present in many skin diseases and, in certain conditions, may constitute part of the diagnostic histopathology. Although eosinophils in general may not be prominent in many cutaneous diseases, ample evidence now shows that they may nevertheless participate in the pathogenesis of cutaneous inflammation and contribute to edematous reactions in atopic dermatitis, syndromes associated with acute and chronic urticarias, IgE-mediated late-phase reactions, chronic dermatitis associated with parasitic infections (such as onchocerciasis, episodic angioedema with eosinophilia, eosinophilic cellulitis), and skin lesions associated with rIL-2 administration for advanced malignancies. Indirect evidence includes the ability of the eosinophil to elaborate its granule cationic proteins (some of which are capable of inducing release of vasoactive amines from basophils and mast cells and inducing cutaneous wheal-and-flare reactions following direct injection into human skin) and production of lipid mediators such as LTC_4 and PAF, both potent inducers of vascular permeability in vivo. In addition, levels of eosinophil-active IL-5 are elevated in patients who have episodic angioedema with eosinophilia and those who have eosinophil-associated toxicity due to IL-2 administration, as well as in the acute inflammatory response (Mazzotti reaction) in human patients with onchocerciasis treated with diethylcarbamazine.

By far, the most conclusive evidence for eosinophil participation in the etiology of the skin diseases remains the immunochemical analysis of skin biopsies showing prominent extracellular deposits of eosinophil granule cationic proteins such as MBP, ECP, or EDN, but not neutrophil products (neutrophil elastase), in affected but not unaffected skin, and in the absence of prominent numbers of intact eosinophils in lesional infiltrates. One example is the IgE-mediated late-phase reaction that follows the wheal-and-flare response characteristic of type I, IgE-mediated hypersensitivity. This classic late-phase reaction, which is characterized clinically by erythema, edema, pruritus, and tenderness peaking 6 to 12 hours after intradermal antigen or anti-IgE challenge, involves infiltration by mononuclear cells, neutrophils, basophils, and eosinophils presumably in response to mast cell degranulation, along with extensive extracellular deposition of eosinophil MBP and neutrophil granule products. The secretion and extracellular deposition of eosinophil granule constituents, shown to possess potent cytotoxic and proinflammatory activities in edematous and eczematous lesions, clearly suggests that eosinophils may contribute to the pathogenesis of both acute and chronic skin diseases, including the cutaneous lesions associated with HES. However, studies elucidating the mechanisms that regulate eosinophil recruitment, activation, and secretion in the skin are still needed to more clearly understand the dynamics of eosinophil participation in these cutaneous disorders and to identify potential therapeutic approaches to selectively block their influx and function.

NEW DEFINITIONS OF HYPEREOSINOPHILIC SYNDROME

HES is not a monolithic diagnosis but a clinical syndrome that can be attributed to a variety of distinct pathologic mechanisms (see box on Diagnosis and Workup of Hypereosinophilic Syndrome). At least two pathogenetic forms of HES—myeloproliferative and lymphocytic variants—have been defined. The MPN form of HES is characterized by hepatosplenomegaly, circulating myeloid precursors, increased serum tryptase levels, anemia, thrombocytopenia, marrow fibrosis, immature myeloid marrow precursor cells, and genetic and cytogenetic abnormalities associated with myeloid neoplasms. These disorders can be accompanied by mutations in PDGFRA, PDGFRB, or FGFR in as few as 10% to 20% of patients with HES. The discovery of these genetic lesions was prompted by reports indicating that some patients with HES or CEL respond to imatinib mesylate with complete hematologic and cytogenetic remissions—in most patients, remission was achieved at fourfold lower doses than those typically used to treat chronic myelogenous leukemia (CML) (100 mg/day versus 400 mg/day). These data suggested that these BCR-ABL–negative patients might possess abnormal gene fusion products or activating mutations that generate novel tyrosine kinase targets of imatinib. These findings sparked a "reverse" bedside-to-bench translational research effort by several research laboratories to rapidly identify the constitutively active tyrosine kinase targets of imatinib in these HES patients. Possible targets included the known activated kinases such as ABL, PDGFR, or c-KIT, all of which had been shown to be inhibited by imatinib mesylate. These efforts led to the successful identification of an activated tyrosine kinase gene fusion on chromosome 4q12, which is produced by a novel interstitial chromosomal deletion of the CHIC2 domain, fusing an uncharacterized human gene known as FIP1-like-1 (FIP1L1) to the platelet-derived growth factor receptor-α gene (PDGFRα). These findings have significantly changed the current paradigm for the diagnosis and treatment of patients with HES and CEL.[13] Of importance, not all HES and CEL patients respond to imatinib, and the majority of patients who do respond with hematologic remissions have been male and not female. It is also important to note that approximately 40% of the patients who do respond to imatinib lack the FIP1L1-PDGFRA gene fusion, suggesting genetic heterogeneity in HES/CEL, which led to the discovery of activating mutations in PDGFRA and PDGFRB that generate imatinib-sensitive constitutively active tyrosine kinases. The FIP1L1-PDGFRA can be detected by fluorescence in situ hybridization (FISH) or by nested polymerase chain reaction (PCR) but not by classical cytogenetics. Eosinophilia is the hallmark of this disorder; it is a multisystem disorder with manifestations secondary to infiltration of tissues with eosinophils and release of proinflammatory mediators and toxic granules. Endomyocardial fibrosis and restrictive cardiomyopathy are the most life-threatening consequences of F1PL1-PDGFRA–positive MPN. PDGFRB fusion partners remain uncommon causes of clonal eosinophilia, which occurs more commonly in men in their late 40s. The disorders associated with these abnormalities are also responsive to imatinib.

The mechanism of action by which the FIP1L1-PDGFRA gene fusion leads to the proliferation and differentiation of the eosinophil lineage over other myeloid lineages in these patients is unclear. Initial investigations suggested that STAT5 may be one of the downstream targets of FIP1L1-PDFGRA tyrosine kinase activity. Studies have demonstrated that retroviral transduction-mediated overexpression of STAT5a in umbilical cord blood–derived $CD34^+$ human stem/progenitor cells selectively amplifies their commitment, proliferation, and terminal differentiation to the eosinophil lineage in vitro in the presence of IL-5 and that STAT5 activation by tyrosine kinases such as BCR-ABL can contribute to the transformation of leukemic cells. A murine transgenic model revealed that the FIP1L1-PDGFRA

Diagnosis and Workup of Hypereosinophilic Syndrome

Patients presenting with eosinophilia of unknown etiology should undergo a thorough clinical and laboratory evaluation consisting of the following:

- Complete/detailed history and physical examination
- Review of all medications (including herbal medications and nutritional supplements); withdrawal of all noncritical medications
- Complete blood count with total eosinophil count and review of peripheral blood smear
- Hepatic and renal function tests, urine analysis
- Vitamin B_{12} level
- Serologic assays: erythrocyte sedimentation rate, rheumatoid factor, human immunodeficiency virus (HIV)
- Serum tryptase level
- Quantitation of total IgE level
- Cardiac troponin level
- Stool for ova, parasites ×3
- Serologic assays for *Strongyloides, Trichinella, Toxocara, Entamoeba histolytica, Echinococcus,* filariasis, and schistosomiasis
- Bone marrow aspirate and biopsy
- Cytogenetics, FISH, and molecular analyses (PDGFRA, PDGFRB, FGFR1 fusion genes, BCR-ABL, JAK2 V617F, KIT D816V, clonal TCR gene rearrangement)
- T-cell phenotyping by flow cytometry
- Chest radiograph; computed tomographic scan of chest, abdomen, and pelvis
- Electrocardiogram and echocardiogram
- Pulmonary function tests

Diagnostic Criteria for HES/CEL

1. Persistent eosinophilia of greater than 1500 eosinophils/mm^3 for more than 6 months
2. Exclusion of other potential "reactive" etiologies for the eosinophilia including parasitic, allergic, or other causes, *and*
3. Presumptive signs and symptoms of organ system dysfunction or involvement that appears related to the eosinophilia or is of unknown cause in the clinical presentation

fusion gene itself is not sufficient to induce an HES/CEL–like disease independently; rather, it requires a second event, that is, overexpression of IL-5.

Eosinophilic disorders due to fusions of FGFR1 are rare but affect patients of all ages with a slight male predominance. This disorder is defined by the rearrangement of the FGFR1 at the chromosome 8p11-12 locus resulting in the creation of fusion proteins with constitutive activation of FGFR1 tyrosine kinase. The most common translocations include t(8;13)(p11;q12); t(6;8)(q27;p11); t(8,9)(p12;q33). The clinical pictures associated with these fusion proteins are quite diverse. Patients with t(8;13)(p11q12) often present with leukocytosis and basophilia rather than eosinophilia and develop lymphadenopathy and T-cell lymphoma, whereas patients with t(6;8) develop disease associated with hypereosinophilia and tonsillar involvement and monocytosis. These disorders are extremely rare and are associated with a poor prognosis with an overall survival of 16 months. These disorders do not respond to imatinib and the few long-term survivors have received allogeneic stem cell transplants. The characteristic genetic abnormalities are best detected using FISH or PCR rather than classical cytogenetics.

CEL-NOS is an MPN defined by a high degree of eosinophilia associated with HES but absence of PDGFRA, PDGFRB, and FGFR1 rearrangements and greater than 2% blasts in the peripheral blood or greater than 5% but less than 20% blasts in the marrow and/or evidence of clonality due to the presence of cytogenetic abnormalities. CEL-NOS is a rare disorder that has been observed in 12.5% of patients with MDS and is associated with a poorer prognosis than other forms of MDS. Progression to blastic transformation (>20% blast cells) in patients with stable disease has been documented. Idiopathic HES is diagnosed in those patients with profound eosinophilia and accompanying tissue damage but no evidence of reactive hypereosinophilia or clonal eosinophilopoiesis. These patients account for 65% to 80% of patients with HES.

Other Genetic Abnormalities Associated With HES

Other TK fusion genes, for example, involving ABL or JAK2, have also been reported in diverse eosinophilia-associated myeloid neoplasms. Disorders with FGFR1 and JAK2 fusion genes are resistant to imatinib and other clinically available tyrosine kinase inhibitors. Fusion genes involving FLT3 are uncommon. An ETV6-FLT3 fusion has been identified in several patients with an eosinophilia-associated MPN who achieved rapid complete hematologic response and complete cytogenetic response after 3 months of taking sunitinib. A secondary blast phase caused by clonal evolution was diagnosed after 6 months, and a second complete hematologic response after taking sorafenib occurred but the patient relapsed 2 months later. A second heavily-pretreated patient with an initial diagnosis of T-lymphoblastic lymphoma and died from sunitinib-induced pancytopenia. Patients with systemic mastocytosis (SM) carry the D816V KIT mutation. Even though these patients often present with features similar to patients with hypereosinophilia, the FIP1L1-PDGFR1 fusion and D816V KIT mutation appear to be mutually exclusive oncogenic lesions. The presence of KIT mutation places these patients into the SM diagnostic category.

Lymphomas and Hypereosinophilia

A number of lymphomas may be associated with the development of eosinophilia, including Hodgkin lymphoma, T-cell lymphoblastic lymphoma, and adult T-cell leukemia/lymphoma, but the eosinophilia is generally much more modest than that seen in HES.[14] In contrast, there are several reports of patients presenting with classic clinical and hematologic features of HES who have gone on to develop acute lymphoblastic leukemia or T-cell lymphoma. In a number of T-cell lymphoma cases, the accompanying eosinophilias were shown to be associated with the production of eosinophilopoietic cytokines (GM-CSF, IL-3, or IL-5) by the lymphoma cells. Most T-cell malignancies associated with eosinophilias have acquired the ability to produce cytokines capable of promoting eosinophilopoiesis. A significant number of patients with peripheral T-cell lymphomas, including Sezary syndrome and mycosis fungoides, develop reactive blood eosinophilia above 700/microliter, which serves as a poor prognostic factor. Eosinophil-mediated end-organ damage is rare in this situation. Eosinophilia is an uncommon finding in patients with B-cell lymphomas, with the exception of Hodgkin lymphoma. Mild peripheral blood eosinophilia has been observed in about 15% of patients with Hodgkin lymphoma with the Reed-Sternberg cells being responsible for excessive IL-5 production. An extreme reactive form of eosinophilia can be associated with rare cases of B-cell acute lymphoblastic leukemia. In 10% of such cases, a t(5;14) translocation is associated with high levels of IL-3. These patients have extreme eosinophilia and can develop eosinophil-mediated end-organ damage. Congestive heart failure occurs in 30% of patients at diagnosis and can be rapidly reversed with the administration of steroids. Effective treatment of this B-cell ALL results in disappearance of the hypereosinophilia, which reappears if relapse occurs.

The Lymphocytic Variant of HES

The lymphocytic variant of HES (L-HES) represents a distinct clinical entity characterized by the overproduction of cytokines capable

of promoting eosinophilopoiesis, primarily IL-5, by an aberrant T-cell phenotype ($CD3^-CD4^+$), and the presence of clonal rearrangements of the T-cell receptor in some, but not all, patients.[15] This syndrome can precede the development of overt T-cell lymphoma. Involvement of the skin is the most common presenting symptom. Serum elevation of IgE and the chemokine TARC is common. The variant occurs equally in males and females and is characterized by skin involvement, gastrointestinal symptoms, obstructive lung disease, and rarely, endomyocardial fibrosis. This variant accounts for 10% to 15% of HES patients. Rare patients have cyclical angioedema and eosinophilia accompanied by cyclical increases of IL-4, suggesting that this is a variant of L-HES. These patients characteristically respond to steroids and not imatinib.

Eosinophil Leukemia

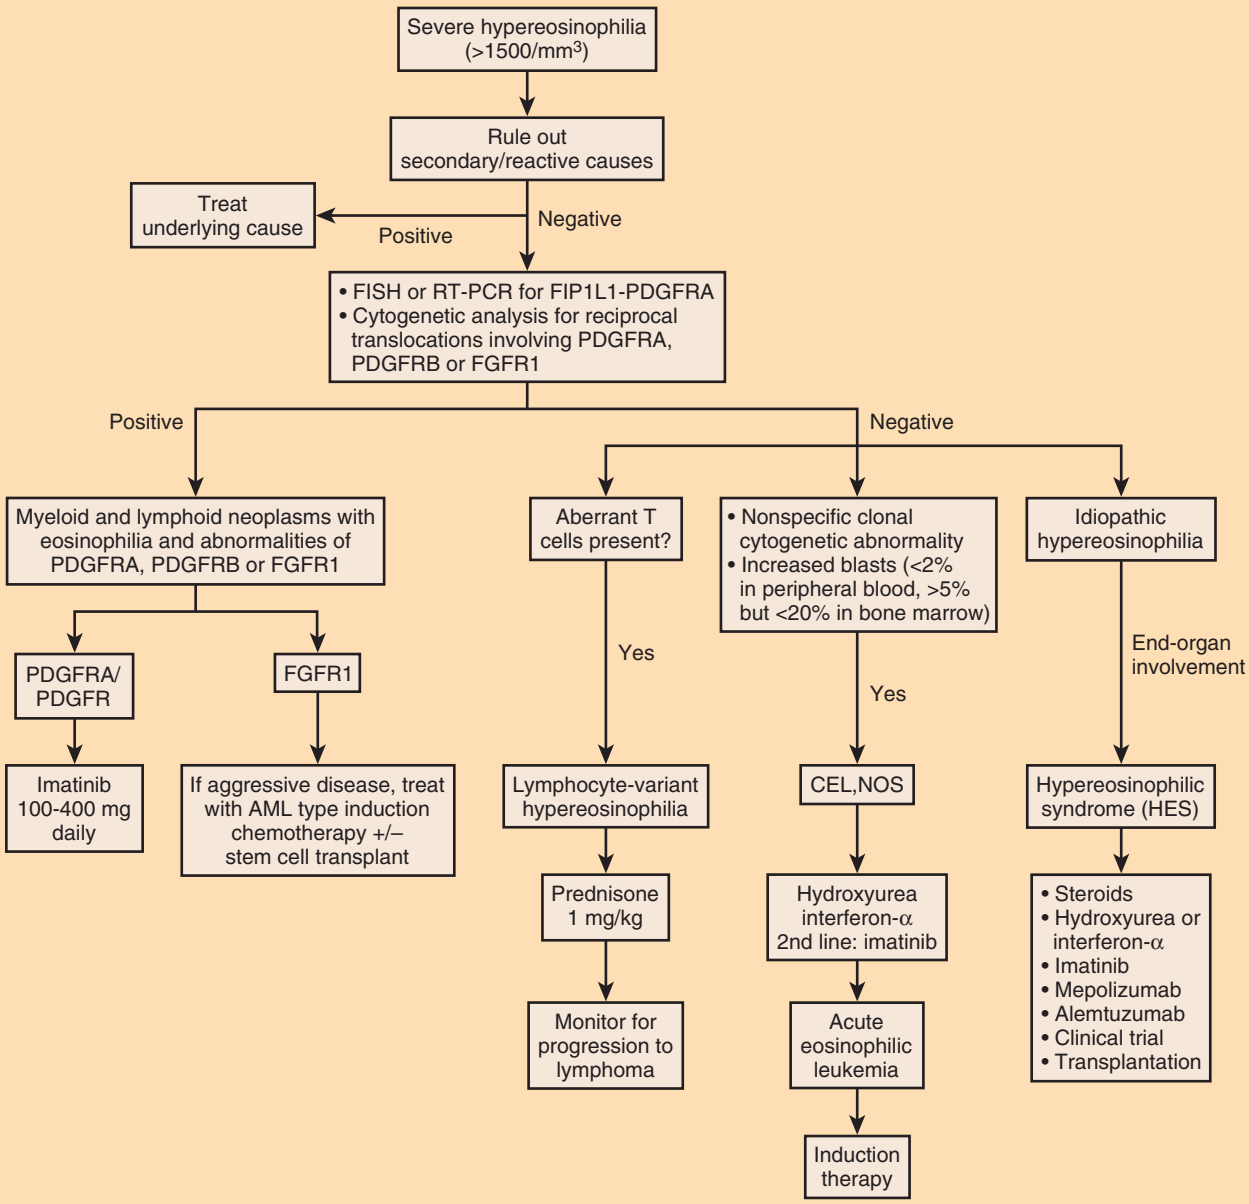
True acute eosinophilic leukemias have several distinguishing characteristics such as a marked increase in the numbers of immature blood and/or bone marrow eosinophils, greater than 20% blast forms in the bone marrow, tissue infiltration with immature eosinophilic cells, and a clinical course and findings that tend to resemble other acute leukemias, including anemia, thrombocytopenia, and increased susceptibility to infections. However, the cardiac and neurologic manifestations of HES can also develop in eosinophil leukemia.

In contrast, CNS infiltration by eosinophils and the tendency to produce bone myeloblastomas are features more frequently associated with acute eosinophil leukemia. Chromosomal abnormalities may occur with both HES and CES-NOS, but eosinophil leukemia is more frequently associated with chromosomal anomalies characteristic of other acute myeloid leukemias including 8:21 and 10p+11q– translocations and trisomy 1. In addition, eosinophil leukemia has been reported as a variant of the M4Eo phenotype of acute myelomonocytic leukemia with eosinophilia, linked to inversion of chromosome 16.

Familial Eosinophilia

Familial clustering of HES is extremely rare but has been observed with Churg-Strauss syndrome and eosinophilic esophagitis. In one family, multiple family members had marked eosinophilia from birth, but only a minority of family members developed symptomatic HES with cardiac involvement.

THERAPY AND PROGNOSIS FOR HYPEREOSINOPHILIC SYNDROME



The earlier literature on HES is filled with reports of poor to dismal patient prognosis. For example, a 1975 review indicated an average survival time of 9 months, with a 3-year survival of only 12%. The high morbidity and mortality likely reflect the fact that most HES patients tended to present late with more advanced disease, in particular, significant cardiovascular problems. Deaths in these patients were generally the result of congestive heart failure and secondary complications of endomyocardial disease, including bacterial endocarditis, progressive valvular incompetence, and the thromboembolic sequelae. However, earlier diagnosis of HES, improved clinical and echocardiographic methods for monitoring, and the use of cardiac medications and cardiothoracic surgical procedures not previously available have resulted in more successful prevention and management of cardiac disease in these patients, considerably improving clinical outcomes and survival. A report in 1989 of 40 HES patients reported 80% survival after 5 years and 42% survival at 10 and 15 years. Thus for many patients, prevention and management of HES end-organ damage, in particular the cardiac sequelae, result in prolonged survival persisting over decades. Supportive therapies for managing the cardiovascular complications of HES, along with therapies aimed at controlling the eosinophilia to prevent end-organ damage, are the mainstay of HES treatment regimens. Treatment should focus on controlling end-organ damage, not just on suppressing or eradicating the eosinophilia, especially as the severity of cardiovascular complications of HES does not necessarily correlate with the duration or level of eosinophilia. Although more aggressive treatment (e.g., cytotoxic chemotherapy or bone marrow transplant) may be indicated in selected patients, the current goal is chronic maintenance therapy. Clearly, all causes of reversible eosinophilia, such as parasite infections, should be treated after careful documentation of the infectious agent. The most prudent approach to treating patients with Churg-Strauss syndrome is to have biopsy-proven disease before embarking on a regimen of high-dose corticosteroids and cyclophosphamide. After achievement of a clinical response or remission, a low dose of prednisone is suggested as maintenance therapy. If unacceptably high doses of prednisone are required for disease control, methotrexate as a maintenance agent is recommended. Interferon alpha or the anti-IL-5 neutralizing antibody mepolizumab also permit the reduction of steroids to more acceptable levels.

Initial Therapeutic Options

It is difficult to predict the duration and severity of eosinophilia that predispose individual patients to end-organ damage. Generally, patients meeting the diagnostic criteria for HES (see Table 70-3), without any overt evidence of organ dysfunction or severe symptoms and with eosinophil counts less than 1500 to 2000 eosinophils/mm^3, can be monitored closely and periodically without treatment for at least 6 months and possibly indefinitely, as long as their complete blood counts are stable, their echocardiograms normal, and no new clinical signs or symptoms of end-organ involvement appear. Periodic reinvestigation of the etiology of the eosinophilia is highly appropriate and recommended every 3 to 6 months to reconfirm the diagnosis of HES. Given the poor prognosis for patients with HES, those patients who have PDGFRA/B abnormalities should be treated with imatinib even in the absence of end-organ dysfunction since this treatment is so effective[16] (see box [flowchart] on Treatment Algorithm for Patients With Severe Eosinophilia). The hematologic benefit of imatinib in FIP1L1-PDGFRA–positive HES has been confirmed in multiple studies. The optimal treatment and dosing strategy for imatinib is not fully defined, and a number of different studies have been performed with imatinib dosing ranging from 100 mg to 400 mg daily. A daily dose of 100 mg appears to be sufficient to induce complete hematologic and molecular remission in most patients, although some patients require doses of up to 400 mg daily. Maintenance doses of 100 to 200 mg weekly may be effective in achieving molecular remission in some patients.[17] The efficacy of imatinib in patients with FIP1L1-PDGFRA HES was evaluated in a multicenter prospective study in an Italian prospective cohort of 27 patients with a median follow-up period of 25 months.[18] Complete hematologic remission was achieved in all patients within 1 month, and all patients achieved complete molecular remission after a median of 3 months of treatment. Patients on imatinib remained PCR-negative during a median follow-up of 19 months. Despite the durable molecular remissions observed in these patients, discontinuation of the drug leads to relapse of the disease.[19] Molecular remissions can be achieved again upon reintroduction of imatinib. Second-generation tyrosine kinase inhibitors such as nilotinib or dasatinib are effective in patients intolerant of imatinib. Frequently, patients resistant to imatinib experience a response with interferon α, but they should be considered candidates for allogeneic stem cell transplantation.

Overall, imatinib is well tolerated at the low dose of 100 mg daily with minimal hematologic and nonhematologic toxicities. However, in a few cases, development of severe left ventricular dysfunction has been reported soon after treatment initiation. Close monitoring of patients is recommended during this time period. Currently, prophylactic use of steroids during the first 7 to 10 days of imatinib treatment is recommended for patients with known cardiac disease. Unlike the experience of patients with CML, only rare cases of imatinib resistance have been described in the 10 years of treating

Treatment Algorithm for Patients With Severe Eosinophilia

Modified from Gotlib J: World Health Organization-defined eosinophilic disorders: 2011 update on diagnosis, risk stratification, and management. *Am J Hematol* 86:677, 2011.

FIP1L1-PDGFR positive disease. Most of the mutations are the T674I mutation within the ATP-binding domain of PDGFRα and occur during the blast phase of the disease. This mutation is analogous to the T315I BCR-ABL mutation in CML, which renders it resistant to imatinib, nilotinib, and dasatinib.

In patients with rearrangement variants other than FIP1L1-PDGFRA, literature (consisting of case reports and small case series) indicates that treatment with imatinib at 400 mg daily can result in durable hematologic and cytogenetic remissions.[20] In patients with FGFR1 mutations, imatinib is not an effective treatment option and thus is not recommended. In many of these patients, the disease follows an aggressive course, often culminating in AML in 1 to 2 years. Therefore intensive chemotherapy followed by allogeneic stem cell transplantation is recommended. Imatinib at doses of 400 to 500 mg/day may also be considered for FIP1L1-PDGFRA mutation–negative patients with myeloproliferative features of disease such as elevated serum tryptase. Only 23% of such patients who receive imatinib experience complete or partial response. Occasionally sorafenib and other second-generation tyrosine kinase inhibitors have been used successfully to treat imatinib resistance. No reports of cure with imatinib have been reported. Patients may remain in remission for some months after discontinuation of therapy; however, eventual relapse is inevitable. Molecular monitoring for detection of minimal residual disease in patients on a constant dose of imatinib is recommended in order to detect early relapse, which should prompt an immediate increase in imatinib dose.

For the majority of hypereosinophilic patients with strictly an idiopathic form of HES (including the absence of abnormalities of PDGFRA, PDGFRB, and FGFR1) corticosteroids (usually prednisone at 1 mg/kg) is considered frontline therapy and is usually effective in achieving rapid reductions in the eosinophil count. Steroids act through the glucocorticoid receptors that are present in the cytoplasm of eosinophils. The mechanisms of action by which corticosteroids induce eosinopenia are multiple and not completely understood. Possible

mechanisms include disruption of eosinophilopoiesis, induction of apoptosis, eosinophil sequestration into the spleen or lymph nodes and reduction of eosinophil chemotactic signals. In a retrospective study of 188 patients with HES, 141 patients (75%) received corticosteroids as initial monotherapy, and 120 (85%) experienced a complete or partial response after 1 month of treatment.[21] The median maximal daily dose of prednisone was 40 mg. Most patients (72%) were maintained on corticosteroids for some time, ranging from 2 months to 20 years, with a median maintenance dose of 10 mg daily. Even though corticosteroids are very effective in rapidly reducing eosinophil counts especially at high doses, chronic use of high-dose steroids is often limited because of the high likelihood of serious adverse effects and long-term toxicity. Generally, once reduction of the eosinophil count to below 1500/mm^3 and symptom control have been achieved, the corticosteroid dose can be tapered. Increases in eosinophil numbers on a prednisone dose greater than 10 mg daily and/or reappearance of symptoms or signs of organ damage are indications for addition of other agents to the steroid regimen.

Corticosteroids are currently the firstline treatment for the lymphocytic variant of HES. Patients with L-HES have a clonal population of T cells with an aberrant immunophenotype and overproduction of IL-5, leading to polyclonal expansion of eosinophils. Elevated serum IgE levels are further associated with responsiveness to steroids in L-HES.

Hydroxyurea (0.5-2 g/day) has demonstrated efficacy in steroid-nonresponsive patients. This drug can also be an effective agent for patients intolerant of corticosteroids, or it can be used in conjunction with corticosteroids as a steroid-sparing medication. A typical starting dose is 500 to 1000 mg daily. In one retrospective study, hydroxyurea was used in 34% of patients. Among 18 patients receiving hydroxyurea as monotherapy, 13 patients achieved either complete or partial response. In combination with corticosteroids, the overall response rate was 69%.[21]

Eosinophil counts begin to diminish after 7 to 14 days of hydroxyurea treatment, reflecting the kinetics of eosinophil development and turnover in these patients. Hydroxyurea interferes with DNA synthesis, thereby inhibiting the development of all marrow-derived cells, in addition to eosinophils. The development of anemia and thrombocytopenia as a consequence of hydroxyurea may necessitate red cell transfusions and decreased doses or cessation of therapy. Weekly leukocyte counts may be necessary to monitor idiosyncratic fluctuations in red blood cell or platelet counts, as well as for consequent adjustment of hydroxyurea dosage.

Interferon-α (INF-α) has been used for the treatment of HES for more than 25 years, both as monotherapy and in combination with other agents. Multiple reports have demonstrated successful management of hypereosinophilia and associated organ damage for patients in whom treatment with prednisone and hydroxyurea has failed. In a retrospective study, 46 of 188 patients received IFN-α either as monotherapy or in combination with another agent—response rates were 50% as monotherapy and 75% in combination.[21] The optimal starting dose of INF-α has not been defined, but the initial dose required to induce normalization of eosinophil count is often higher than the dose required to maintain remission. Usually, therapy is initiated at 1 million units three times weekly by subcutaneous injection, and the dose is titrated up to 3 to 4 million units three times weekly as needed for individual patients to achieve control of the eosinophil count. Improvements in the eosinophil count have been associated with improvement in splenomegaly and hepatomegaly, as well as reductions in cardiac and thromboembolic complications, mucosal ulcers, and skin manifestations. Treatment with pegylated IFN-α-2b on a weekly schedule has also been effective in the treatment of HES.[22] INF-α treatment has been reported to result in cytogenetic remissions in patients with cytogenetic abnormalities. Side effects of short- and long-acting formulations of IFN-α are often dose dependent and include fatigue and flu-like symptoms that often improve with long-term administration and can be easily controlled with acetaminophen. Exacerbation of autoimmune disorders, such as autoimmune thyroiditis, psoriasis, ulcerative colitis, and others have been reported. Exacerbation of depression, including development of suicidal ideation and development of psychosis, is a serious side effect that needs to be carefully assessed at each visit; thus patients with a known history of psychiatric disorders may be deemed ineligible for this medication. Other serious adverse events that have necessitated taking patients off the drug include excessive suppression of blood counts, retinopathy, sarcoidosis, and left-sided heart failure. It is important to note, however, that unlike hydroxyurea, which is a teratogen, IFN-α is considered safe to use in pregnancy.

Receptors for IFN-α are present on eosinophils, although variations in the expression levels exist. In vitro, release of eosinophil-derived neurotoxin and eosinophil cationic protein, by eosinophils activated with IgA and IgE immune complexes, is inhibited by preincubation with IFN-α. In addition, reductions in major basic proteins have been reported in HES patients treated with IFN-α.[23] These eosinophil granule proteins have been shown to have detrimental effects on a number of tissues, including cardiac cells and Purkinje cells; thus one of the effects of IFN-α may be to reduce toxic levels of these proteins in circulation and tissues. Clinical results are also due in part to the effect of IFN-α on eosinophil proliferation, migration, activation, and survival, as well as on its modulation of Th1/2 cytokine profile. IFN-α and IFN-γ promote the development of Th1 subset of clonal CD4$^+$ T cells that secrete IL-2 and IFN-γ. IFN-γ is a proinflammatory cytokine that inhibits differentiation of eosinophils from IL-3– and IL-5–stimulated umbilical cord mononuclear cells, as well as their tissue migration. IFN-α inhibits production of IL-5, TNF-α, and GM-CSF by human cord blood–derived mast cells and inhibits IL-5 production by CD3$^-$CD4$^+$ T cells from patients with HES.

Cyclosporine, an immunosuppressant that interferes with multiple aspects of immunocompetent T-lymphocyte function, has been reported to be effective in some HES patients. The goal of cyclosporine treatment in HES is to inhibit production of eosinophilopoietic cytokines (i.e., IL-5) by putative T-cell clones thought to drive the eosinophilia in these patients. Of interest, T-cell clones have been established and characterized from the peripheral blood of many patients with HES, providing the rationale for its use. Cyclosporine has been used in conjunction with low-dose corticosteroids, although the reported duration of therapy has been limited (10 months) and longer-term efficacy and side effects in HES have not been determined. Corticosteroid-sparing effects and durable control of eosinophilia using 4 mg/kg of cyclosporine in a series of HES patients have been demonstrated.

Anti–IL-5 antibody approaches continue to be actively investigated for the treatment of HES, given the role of this cytokine in eosinophil development, activation, and survival. Mepolizumab is a fully humanized immunoglobulin G1 (IgG1) kappa monoclonal antibody that binds IL-5 and prevents it from binding to the IL-5 receptor alpha chain. Studies with this agent done in HES patients showed regression of constitutional symptoms and dermatologic lesions and improvements in pulmonary function tests. Response has not been predicted by pretreatment IL-5 levels or the presence of FIP1L1-PDGFRA. A 2008 international, randomized, double-blind, placebo-controlled trial of mepolizumab in patients with FIP1L1-PDGFRA–negative HES demonstrated a corticosteroid-sparing effect of mepolizumab.[24] In patients requiring 20 to 60 mg of prednisone per day to maintain eosinophil count less than 1000 per microliter and stable clinical status, 84% of patients in the mepolizumab group (compared with 43% of patients in the placebo group) achieved the primary end point of reduction of the prednisone dose to 10 mg or less for 8 or more consecutive weeks. Rates of adverse events were similar in treated and placebo groups. Mepolizumab is not yet FDA-approved for the treatment of HES but may be available through compassionate use protocol for patients with life-threatening, treatment-resistant disease.

Reslizumab is a humanized IgG4 anti–IL-5 monoclonal antibody that is currently in clinical trials for eosinophilic esophagitis and in pediatric patients for eosinophilic asthma, but it has not yet been evaluated extensively for patients with HES. Early studies showed improvements in eosinophil counts and clinical symptoms in 75% of patients. More studies are needed to evaluate the treatment potential of this antibody.[25]

Alemtuzumab is anti-CD52 monoclonal antibody being evaluated for the treatment of HES based on the rationale that eosinophils express CD52 antigen. It has been used for the treatment of therapy-resistant eosinophilic disorders with variable results.[26] In 10 of 11 patients, alemtuzamab induced hematologic remission; however, this response was not sustained off-therapy.

Historically, a number of cytotoxic agents have been used to treat HES, refractory to steroids and hydroxyurea. The use of these agents is now limited, given the availability of other, more effective and less toxic treatments. Vinca alkaloids are effective in HES, and vincristine (1.0-1.5 mg/m^2 at biweekly intervals), which produces a permanent mitotic arrest by disrupting spindle microtubules, has been shown to be beneficial in some patients. However, the use of vincristine can lead to liver failure and is limited by neurologic complications that may be indistinguishable from the peripheral neuropathies associated with HES. Because vincristine decreases blood eosinophil counts in 1 to 3 days, it may be particularly useful for acute treatment of patients with marked hypereosinophilia (>100,000 eosinophils/mm^3). Other chemotherapeutic agents that have been used with some success in a limited number of patients include etoposide (VP-16) and alkylating agents such as chlorambucil. In particular, etoposide, a podophyllotoxin derivative and topoisomerase II inhibitor that induces DNA damage, has been used successfully in a number of patients to date. Administration of oral followed by parenteral etoposide after cessation of hydroxyurea treatment has been reported to control symptoms and eosinophil counts for prolonged period of 18 months, but its use was ultimately withdrawn because of marrow suppression. Use of oral pulses of chlorambucil has been reported at doses ranging from 4 to 10 mg/m^2 daily for 4 consecutive days approximately every second month for 2 years with some efficacy in patients refractory to steroids and intolerant of hydroxyurea.

Leukapheresis

Plasma and leukapheresis have no defined role in the long-term management of HES. The use of leukapheresis has generally been restricted to emergency situations for patients developing profoundly high eosinophil counts. However, cell counts rebound rapidly to pretreatment levels within 1 day of the procedure. Even multiple repeated sessions of leukapheresis are usually not sufficient to induce more than a transient decrease in blood eosinophil levels. Five repeated plasma and leukapheresis sessions over a period of 2 weeks were reported to significantly decrease blood eosinophilia; however, continued sessions were insufficient by themselves to lower blood eosinophil counts to acceptable levels. The mechanism by which plasmapheresis transiently decreases eosinophil levels is entirely speculative but has been suggested to involve a temporary removal or decrease in the levels of circulating eosinophilopoietic factors.

Anticoagulation and Antiplatelet Agents

Because thrombotic and thromboembolic events are frequently serious complications of HES, anticoagulants have often been used, especially in those patients with clear evidence of thromboemboli, neurologic symptoms, and cardiac involvement. Commonly used agents include warfarin, antiplatelet agents, and heparin. However, the efficacy of anticoagulation or antiplatelet agents has not been clearly established in HES disease, and many patients treated with these agents have continued to have thrombotic events, despite their adequate use.

Splenectomy

As previously noted, splenomegaly has been used in HES patients, and hypersplenism in these individuals may contribute to thrombocytopenia, anemia, and splenic infarction. Splenic pain induced by capsular distention or infarction is a known complication of HES. In HES, splenectomy has the capacity to ameliorate platelet sequestration from hypersplenism and to relieve the pain associated with splenic distention and infarction.

Stem Cell Transplantation

Experience reported with stem cell transplantation for the treatment of HES is quite limited; however, it has been attempted for aggressive and treatment-resistant disease.[27] Reports of stem cell transplantation for refractory HES include several successes with patients apparently in complete remission with the clinical course complicated in some by the development of graft-versus-host-disease (GVHD) requiring cyclosporin-A therapy. In another report, the patient relapsed 40 months after transplantation but survived for more than 44 months. Only in HES cases with an extremely aggressive course unresponsive to standard therapies or in young patients with a refractory course of disease and clinical features suggestive of a myeloproliferative neoplasm (e.g., chromosomal abnormalities) should allogeneic stem cell transplantation be considered a treatment option. Without greater understanding of the underlying mechanisms responsible for the overproduction of eosinophils and the aggressive development of end-organ damage in some of these patients, the risks associated with stem cell transplantation may outweigh its more routine use in treatment of this disorder.

Cardiac Surgery

Treatment of the cardiovascular sequelae of HES continues to be a therapeutic challenge. Surgical intervention in eosinophilic heart disease does not appear to carry any risk for disease recurrence at the operative sites. For patients who develop significant compromise of valvular function, endomyocardial thrombosis, or fibrosis, cardiac surgery has the capacity to provide substantial clinical and quality-of-life improvements. Mitral valve and/or tricuspid valve repair or replacements have been reported in more than 50 eosinophilic patients. Endomyocardectomy and thrombectomy, as performed for advanced-stage Löeffler endomyocardial fibrosis, have also been used effectively in some HES patients, and ventricular decortication may be performed in combination with valve replacement. For mitral valve replacements, mechanical valves have proven problematic because of recurring thrombotic episodes despite adequate anticoagulation, suggesting the use of porcine valves whenever possible. HES patients who have received valve replacements have generally experienced long-term improvement in cardiac function, provided the eosinophilia remains controlled.

FUTURE DIRECTIONS

The heterogeneous nature of HES, ranging from patients with clear features of myeloproliferative disorders (including cytogenetic abnormalities) to patients with more benign clinical courses (such as episodic angioedema with eosinophilia), suggests that multiple disease processes are likely at play. Current research aimed at defining the cause of HES and mechanisms regulating the development of eosinophil-mediated end-organ damage in eosinophil-associated diseases in general should ultimately lead to more selective and improved therapies. The therapeutic targets for these efforts are likely to include (a) IL-5 and its high-affinity receptor; (b) underlying T-cell clones (either immunocompetent or occult T-lymphoid malignancies) that elaborate IL-5 or GM-CSF tissue- or organ-specific dysfunctional elaboration of eosinophil-active chemoattractant factors such as eosinophil-selective chemokines (the eotaxins); (c) vascular endothelial adhesion molecules (VCAM/VLA-4); and (d) undefined mechanisms that induce the overproduction of eosinophils and/or serve to recruit and activate eosinophils selectively in certain tissues and organs.[28] The essential absence of end-organ damage in some syndromes of hypereosinophilia contrasts starkly with the morbidity (and

mortality) associated with the development of endomyocardial fibrosis in HES and certain other eosinophilias. Because HES patients are clearly a heterogeneous group, clinical management based on current knowledge must be specifically tailored to the individual, with the overall goal of controlling the eosinophilia and, in particular, the eosinophil-mediated end-organ damage. The clinical and surgical management of patients with IE and HES has evolved significantly. Current treatment options facilitate the control or eradication of eosinophilia and end-organ damage in most HES patients. The efficacy of imatinib mesylate in patients with HES has led to the identification of the FIP1L1-PDGFRA gene fusion, which encodes a pathogenetically relevant and constitutively active tyrosine kinase. This seminal finding had led to a reclassification of hypereosinophilias into several well-defined clinical entities and has stimulated research that may ultimately translate into improved clinical characterization and therapeutic options. For patients with imatinib-resistant forms of CEL or those with classic HES that does not respond to conventional therapies such as glucocorticoids, hydroxyurea, and IFN-α, treatment options such as stem cell transplantation may hold promise for durable disease remissions. Treatment with IFN-α should be considered as an initial firstline option for the management of imatinib-nonresponsive HES, either alone or in combination with other therapies. Finally, humanized anti–IL-5 antibody (mepolizumab) is available through compassionate use protocols at several institutions. The clinical data with this agent look highly promising for the treatment of a wide range of patients with *FIP1L1-PDGFRA*-negative HES and possibly other eosinophilias—for example, eosinophilic gastrointestinal syndromes such as eosinophilic esophagitis.

Future research on HES and CEL will likely focus on the molecular basis of imatinib responsiveness in both FIP1L1-PDGFRA–positive and –negative patients, specifically addressing how the constitutively activated FIP1L1-PDGFRA or other fusion- or mutant-activated kinases selectively lead to chronic hypereosinophilia and end-organ damage. Studies of the effects of imatinib on the proliferation and terminal differentiation of bone marrow–derived eosinophil progenitors, as well as the survival and intracellular signaling pathways in eosinophils from imatinib-responsive patients, may be particularly revealing in terms of the downstream targets of these novel kinases. Clearly, more carefully controlled clinical trials are required to define evidence-based information with which to treat this patient population.

CHAPTER 71

MAST CELLS AND SYSTEMIC MASTOCYTOSIS

John Mascarenhas, Animesh Pardanani, Marina Kremyanskaya, and Ronald Hoffman

MAST CELLS

Discovery

The discovery of mast cells is credited to Paul Ehrlich, who first described a subgroup of cells ("Mastzellen") localized to a large extent around blood vessels within a number of tissues; these cells were thought to be larger than white blood cells and to contain "protoplasmic deposits" (granules) that reacted in a characteristic manner with aniline dyes. Ehrlich stressed that the identification of mast cells was based primarily on a specific histochemical reaction that rendered the cellular granules metachromatic, not simply on the morphologic appearance of these cells. Several years later, Ehrlich also discovered a peripheral blood basophilic granulocyte in patients with myeloid leukemia and suggested that this cell (blood mast cell, basophil, or mast leukocyte) had its origin in the bone marrow with subsequent residence in the peripheral blood. Mast cell nuclei are typically round to oval, whereas basophils have lobulated nuclei similar to granulocytes.

Origin

Normal mast cells originate from a $CD34^+$ cell population in the bone marrow.[1] Mast cells are released into the circulation in a primitive state and undergo terminal maturation/differentiation after migrating into tissues, where they ultimately reside. Mouse models were first used to investigate the origin and development of mast cells. In a C57BL/6-bg^j/bg^j, beige Chediak-Higashi–syndrome mouse model, the giant mast cell granules were used as a morphologic marker for donor-derived cells. Here, cells from the bone marrow, peripheral blood, liver, thymus, or lymph nodes of beige mice were transplanted into irradiated, congenic C57BL/6 +/+ mice, or alternatively, the beige mouse was parabiosed with a congenic +/+ mouse, dominant white-spotting (W)– or steel (Sl)–locus mutant mice (vide infra) that are profoundly deficient in mast cells. The mast cells in skin and other organs in the adult W/W^v mouse could be restored to normal levels after transplantation with bone marrow cells from congenic +/+ mice.

The relationship between human mast cells and cells belonging to other leukocyte lineages remains unclear. Although mast cells share several features with basophils, namely presence of cytoplasmic basophilic granules, expression of high-affinity IgE receptors (FcεRI), and release of histamine upon stimulation, the two cell types are considered to be distinct. Unlike mast cells, basophils circulate in the blood as mature cells and are thought to be incapable of proliferation; basophils undergo apoptosis after their recruitment and activation in the tissues. Studies of developmental pathways in murine models have not been conclusive as to how mast cell–committed progenitors are generated. It remains uncertain as to whether there is a shared bipotent progenitor for mast cells and basophils or whether mast cells are derived directly from multipotent progenitor cells. Eosinophils and basophils, by contrast, share a common bipotent progenitor cell. However, molecular studies in patients who have received cells from patients with systemic mastocytosis (SM) have revealed that a pathogenetically relevant mutation, Kit Asp816Val (D816V), is found primarily in mast cells and not basophils, thus suggesting that the two cells do not arise from a common progenitor cell. Furthermore, it has been proposed that mast cells and basophils, both of which contain metachromatic granules, can be distinguished on the basis of cellular immunophenotype, gene expression profile, or growth factor responsiveness. The primary cytokine for mast cell growth and differentiation is stem cell factor (SCF)/C-KIT ligand. Other cytokines (including IL-3, IL-4, IL-5, IL-6, and IL-9), however, do not independently promote the generation of mast cells but may enhance the activity of SCF. Mast cells resemble monocytes based on several characteristics, including their responsiveness to IL-4, the expression of mast cell tryptase in human monocytic cell lines, and the ability of murine mast cells to adopt monocytic features in vitro.

Growth, Proliferation, Survival

The interaction between SCF and its cognate receptor C-KIT plays a key role in regulating mast cell growth and differentiation. Kit is expressed on hematopoietic progenitors and is downregulated upon differentiation into mature cells belonging to all lineages, except mast cells, which retain high levels of C-KIT expression. Insight into the biologic function of Kit and SCF has been derived from observations of mice carrying specific mutations at the dominant white-spotting or steel loci, respectively. A double dose of mutant alleles at either locus produces common pleiotropic effects, including a profound decrease in mast cell number, coat color abnormalities/white-spotting (piebaldism), macrocytic anemia, reduced fertility, and abnormalities in intestinal pacemaker activity. Despite the shared phenotype between W- and Sl-mutant mice, the mechanism underlying the defect in hematopoiesis is quite different. In W/W^v mice, for instance, transplantation of bone marrow cells from congenic +/+ mice corrected both the anemia and mast cell deficiency, which indicated the defect was an intrinsic stem cell disorder. Many independent mutations of the W locus have been described; the alleles are semidominant and vary in their phenotypic effect on hematopoiesis, pigmentation, and fertility in the homozygous and heterozygous state. By contrast, the defect is cell-extrinsic in Sl/Sl^d mice; when skin from either W/W^v or Sl/Sl^d mice was grafted onto the back of congenic +/+ mice, mast cells were found to populate the grafted skin from W/W^v mice but not in skin from Sl/Sl^d mice. Furthermore, the hematologic defects in Sl/Sl^d mice were not corrected by transplantation of bone marrow cells from a congenic +/+ host, indicating that the disorder is microenvironmental in nature.

Activation and Function

Mast cells are ubiquitous and are found in virtually all tissues, but they are most numerous at anatomic sites that are in contact with the environment, such as the mucosa of airways and gut, as well as in the skin. Although mast cells have been long identified as key cellular mediators of the allergic inflammatory response, they have a myriad of other physiologic functions, including a key role in innate immunity. The study of mast cell function in humans has been difficult for

several reasons. First, these cells are relatively inaccessible; in general, primary culture of mast cells (including those derived from cord blood or peripheral blood–derived progenitor cells) is cumbersome, the yield of cells is quite limited, and it is presently unclear whether fully mature mast cells can be obtained by this approach. Second, there appears to be significant variation in the functional properties of mast cells depending on the anatomic location from which they are isolated (e.g., skin versus intestinal mucosa). Third, mast cells display considerable phenotypic plasticity, with many autocrine, paracrine, or systemic factors influencing various aspects of cell phenotype. Consequently, investigators have often relied on transformed mast cell leukemia cell lines (e.g., HMC-1, LAD-1, LAD-2) or murine animal models for experimental studies of mast cell function. Mouse strains that exhibit a profound mast cell deficiency include (a) C-KIT/W mutant mice (e.g., W/W^v mice; vide infra) also display non–mast cell phenotypic abnormalities including sterility, which entails complex breeding strategies, and (b) W^{sh}/W^{sh} mice, which carry an inversion mutation upstream of the C-KIT coding region, display abnormal pigmentation and reduced mast cell number but have relatively preserved hematopoiesis and fertility. The aforementioned mice can be selectively reconstituted with mast cells by systemic (intravenous) or local (e.g., intradermal, intraperitoneal) transfer; this adoptive transfer of genetically compatible, in vitro cultured mast cells (e.g., from bone marrow cells) provides a useful model (i.e., "mast cell knock-in mice") for the study of mast cell function in vivo. It remains unclear, however, whether observations generated using cell lines or mouse experiments can be extrapolated to humans, given that neoplastic transformation significantly alters normal cellular function and the marked interspecies differences in mast cell biology. Mast cells undergo activation, classically following cross-linking of FcεRI-bound IgE by multivalent allergens in sensitized individuals. The tissue mast cell burden is dynamic and has been noted to increase in chronic allergic inflammatory states. Non-IgE triggers for mast cell mediator release include anaphylatoxins of the complement system (C3a and C5a), neuropeptides (e.g., vasoactive peptides, somatostatin, substance P), proteoglycans (heparin), prostaglandins, lipopolysaccharides, chemokines (e.g., CCL3, MIP1α), Toll-like receptors, proteases (tryptase, chymase, carboxypeptidase) and cytokines (TNF). Other non-IgE triggers for mast cell activation include specific cytokines, such as SCF, and to some extent IL-4 (in cooperation with SCF) as well as IL-3. Upon activation by either IgE-dependent or IgE-independent mechanisms, these mediators are released. Mast cells are primed for multiple cycles of degranulation-mediator release, and display distinct patterns of mediator release depending upon the strength and type of stimulus that is provided. Mast cells display a wide spectrum of "activation levels" in vivo; however, the mechanisms regulating the secretory phenotype of mast cells in a given individual is not completely understood. The key mast cell mediators include (a) vasoactive amines, particularly histamine; (b) several distinct tryptases (α, β, and γ) that comprise the principal protein component of mast cells; (c) anionic proteoglycans (e.g., heparin, chondroitin sulphate) that confer metachromasia upon staining with toluidine blue; (d) various lipid mediators; these arachidonic acid-derived eicosanoids, which include leukotriene C_4, leukotriene B_4, and prostaglandin D_2, mediate vasodilation, vasopermeability, smooth muscle constriction, mucus secretion, as well as other proinflammatory processes; (e) other proteases (e.g., chymase, carboxypeptidase A); and (f) specific cytokines. The secreted cytokines, which recruit and activate specific cells, include IL-3 (basophils), IL-5 (eosinophils), tumor necrosis factor-α/IL-8 (neutrophils), and IL-4/IL-13 (T and B lymphocytes). Mast cells mediate not only early-phase (e.g., anaphylaxis, acute asthma) but also late-phase allergic responses, as well as non–type I hypersensitivity reactions through the aforementioned mediators. Furthermore, mast cells mediate upregulation of T_H2-responses and allergen-specific IgE biosynthesis, which contribute to host defenses against parasitic infections. Mast cells have also been implicated in other nonallergic diseases, including viral and bacterial infections, autoimmune disorders, as well as in angiogenesis related to cancer, although their role(s) in these conditions has not yet been precisely delineated.

Role of C-KIT and Stem Cell Factor in Mast Cell Biology

C-KIT is the cellular homolog of the V-KIT oncogene of the Hardy-Zuckerman 4 feline sarcoma virus and encodes for Kit, which belongs to the type III subfamily of receptor tyrosine kinases. Members of this receptor tyrosine kinase subfamily share both sequence similarity and a common overall structure, with an extracellular domain containing five immunoglobulin-like motifs that bind SCF, a short transmembrane (TM) domain that anchors Kit to the cell membrane, a cytoplasmic tyrosine kinase (TK) domain that is split by an insert sequence into ATP-binding and phosphotransferase regions, and a juxtamembrane (JM) domain that lies between the TM and TK domains. C-KIT is located on human chromosome 4, in a region (4q11-q12) homologous to a region of mouse chromosome 5, that includes the W gene locus. Additional studies sought to determine whether the W locus was linked to murine C-KIT.[2] Using interspecific backcross analyses, the two were shown to be tightly linked, and C-KIT was subsequently found to be disrupted in two spontaneous mutant W alleles, W^x, and W, confirming that Kit was encoded by the W locus. Specific mutations at the W locus, such as W (78, amino acid TM/JM deletion), W^{37} (JM missense mutation), or W^v, W^{41}, and W^{42} (TK missense mutations), result in a loss-of-function phenotype and point to the critical role of individual domains/regions in Kit function. The common phenotypic denominator of mutations at the W locus is reduced Kit tyrosine kinase activity, whether by expression of decreased numbers of Kit receptors with normal kinase activity (W^{44}, W^{57}, and W^x alleles) or expression of normal numbers of kinase-defective Kit (W^{37}, W^{42}, W^{41}, W^v, W^{55} alleles).

SCF was initially isolated from medium conditioned by Buffalo rat liver cells and exhibited ex vivo growth factor activity toward primitive hematopoietic progenitors, as well as mast cells. The subsequent purification, cloning, and mapping of SCF revealed it to be syntenic with the Sl locus on mouse chromosome 10, and SCF sequences were found to be deleted in a number of mutant Sl alleles such as Sl^d and Sl^{12H}. SCF was shown to be a ligand for Kit by cross-linking of ^{125}I-labeled SCF to Kit-expressing cells, and the administration of recombinant SCF in vivo rescued both the macrocytic anemia and the mast cell deficiency exhibited by Sl/Sl^d mice. The steel-Dickie (Sl^d) mutation is a 4.0-kb deletion within the gene SCF, which renders Sl^d capable only of encoding a soluble truncated growth factor that lacks both transmembrane and cytoplasmic domains. SCF is synthesized by a variety of mesenchymal cells, including fibroblasts, that express the cytokine as a transmembrane protein that may be proteolytically cleaved to generate a soluble form; two distinct isoforms with differential susceptibility to proteolysis are synthesized. Soluble SCF exists as a homodimer in plasma and can crosslink two Kit receptors on the cell surface, thereby leading to activation of Kit, as well as downstream signal transduction. SCF promotes mast cell development, survival of mature mast cells, as well as adhesion of mast cells to extracellular matrix proteins. SCF also regulates mediator release from human mast cells, potentially by both IgE-dependent and IgE-independent mechanisms.

Mast cells and eosinophils frequently are each present in atopic disorders such as allergic disorders, atopic dermatitis, and asthma. Mast cells provide the intermediate stimuli upon activation that leads to eosinophil recruitment. Both mast cells and eosinophils express CCR3 and respond to eotaxins and CCL5 (RANTES), leading to localization of both cell types to inflamed tissues. Eosinophils can produce SCF, which can attract more mast cells and delay their apoptosis. This cross-talk between eosinophils and mast cells plays a key role in the activation and eventual downregulation of inflammation.

SYSTEMIC MASTOCYTOSIS

SM is a clonal hematologic malignancy that has been included as a myeloproliferative neoplasm and is characterized by the excessive growth and accumulation of immunophenotypically abnormal mast cells in one or more tissues. The bone marrow is involved in almost

all cases. The clinical features and course of SM vary widely from an indolent form associated with a normal life expectancy to a highly aggressive form associated with organ failure and a short survival. In contrast to normal mast cells, neoplastic mast cells are more variable in appearance, ranging from round to fusiform variants, with long, polar cytoplasmic processes; they additionally display cytoplasmic hypogranularity with uneven distribution of fine granules, as well as atypical nuclei with monocytoid appearance.[3] Immunophenotypic evaluation of mast cells reveals frequent expression of aberrant markers in SM patients.

Epidemiology

Epidemiologic data on SM are scarce. The true incidence of this rare group of heterogeneous disorders is unknown, and SM is considered an orphan disease in the United States that affects all ethnic groups equally. CM is more common in children than in adults, and it is usually transient and self-limited. A slight male predominance has been observed, and the median age at time of SM diagnosis was 55. The median survival of this cohort of SM patients was 63 months, which is inferior to the age- and sex-matched U.S. population with the exception of ISM, which carries a normal life expectancy. The excess of deaths occurs in the first 3 years from time of diagnosis.

Pathobiology

Current evidence points to an important role for gain-of-function mutations in C-KIT, particularly Kit D816V, in the pathogenesis of mastocytosis. It remains to be determined whether additional genetic events are necessary for neoplastic transformation of mast cells and for full expression of the mastocytosis phenotype. Other specific mutations, such as FIP1L1-PDGFRA and Kit F522C, although rare, exhibit specific genotype-phenotype associations in mastocytosis patients and hence deserve specific mention in this section.

Kit D816V

Furitsu and colleagues showed that Kit expressed on HMC-1 cells, an immature mast cell line, was constitutively phosphorylated and activated in the absence of SCF.[4] Sequencing of C-KIT in these cells revealed two point mutations, one in the juxtamembrane region at codon 560 and nucleotides 1699-1701 (V560G; GTT → GGT) and the other in the tyrosine kinase at codon 816 and nycleotides 2467-2469 (D816V; GAC → GTC) domain. Two rodent cell lines, P815 (mouse mastocytoma) and RBL-2H3 (rat mast cell leukemia), were subsequently found to possess mutations corresponding to human D816V (i.e., D814Y and D817Y, respectively). These mutations, in human, mouse, and rat Kit, were shown to be constitutively activating when expressed in the human embryonic kidney cell line 293T. Soon after this came the first report of the detection of the Kit D816V mutation in blood mononuclear cells from patients with SM and associated non–mast cell myeloid neoplasms but not in patients with indolent or aggressive SM, solitary mastocytomas, or chronic myelomonocytic leukemia.[5] Point mutations of the Kit are the most common genetic abnormality in SM and result in a substitution of valine for aspartate at codon 816 of exon 17 termed *Asp816Val* or *D816V*. More than 95% of patients with SM have this mutation. Additional Kit mutations, involving D816 or an adjacent amino acid residue (e.g., D816Y, D816F, D816H, I817V or VI815–816, and D820G) or other domains (extracellular, transmembrane, or juxtamembrane) have also been identified in mastocytosis. The juxtamembrane mutations include V560G, K509I, and V559A; some are rare alleles detected in germline DNA in cohorts with familial forms of mastocytosis. Of interest, several kindreds with combined familial gastrointestinal stromal cell tumors and SM, both of which are associated with gain-of-function Kit mutations, have also now been described.

Kit signaling is believed to regulate multiple transcriptional targets through downstream targets, which include PI3K-Akt, the Src family of kinases, Ras/ERK, phospholipase Cγ, MAPK, and JAK-STAT.[6] Both PI3-kinase and Src-kinase signaling pathways converge to activate JNK and RAC1 and bone marrow–derived mast cell proliferation but not apoptosis and require an intact JNK/RAC1 pathway for Kit ligand–induced proliferation of mast cells. Because of the many complex signaling pathways that are activated downstream from Kit, diverse biologic functions such as chemotaxis, differentiation, proliferation, and survival of clonal mast cells are likely influenced by Kit-activating mutations.

Although activating Kit mutations are clearly associated with human mastocytosis, they do not occur universally, and whether individual mutations are necessary and sufficient to cause mast cell transformation remains currently unresolved. Introduction of human Kit D816V (or its murine homologs) into IL-3-dependent cell lines—Ba/F3 (pro–B-lymphocyte), IC-2 (mast cell), or FDC-P1 (myeloid)—results in their cytokine-independent growth. Furthermore, subcutaneous injection of mutant Kit V559G– or Kit D814V–bearing Ba/F3 cells into nude mice led to the appearance of large mastocytomas, with all the mice subsequently dying of mast cell leukemia. These experiments do not, however, provide direct confirmation of the neoplastic transformation potential of activating Kit mutations since the IL-3–dependent cell lines are immortalized and have acquired a priori the capacity to self-renew. Investigators have introduced activated Kit (V559G or D814V) by using retroviral vectors into murine bone marrow cells and injected these cells into mast cell–deficient irradiated W/W^v mice. In vitro colony assays revealed that Kit D814V, and to some extent Kit V559G, resulted in cytokine-independent growth of both mast cell and non–mast cell myeloid colonies. Furthermore, a proportion of the transplanted mice developed acute leukemia, likely of B-lymphoid origin; in addition, a subset of transgenic mice expressing Kit D814V developed acute leukemia/lymphoma of immature B-cell origin at 10 to 80 weeks of age. In another study, human Kit D816V was introduced into murine fetal liver cells, with induction of megakaryocytic differentiation, in the absence of cytokines. In the presence of SCF, Kit D816V–expressing cells showed increased mast cell differentiation, as did Kit–wild-type (WT)–expressing cells. The Kit D816V–expressing cells, however, were not transformed, as assessed by colony assays, regardless of the absence or presence of SCF. Furthermore, introduction of Kit D816V induced both myeloid and mastocytic differentiation patterns of Ba/F3 cells but did not enhance their growth. Thus experimental data from mouse studies conflict as to whether activating Kit mutations are sufficient to cause oncogenic transformation. Similarly, Kit D816V mutation alone may not be sufficient to cause oncogenic transformation in humans. This is consistent with the observation that most mastocytosis patients with this mutation alone have indolent disease. In addition, B cells and monocytes carrying mutated C-KIT display a nonmalignant behavior pattern, despite being derived from the same precursor that gives rise to mast cells within the lesions present in mastocytosis patients. Thus it is possible that Kit D816V may affect the differentiation and apoptosis potential of human mast cells rather than providing a potent proliferative signal. In support of this theory, Kit D816V positive human bone marrow mast cells, but not normal mast cells, survive in vitro in the absence of SCF. Moreover, enhanced expression of the antiapoptotic protein BCL-XL was found in lesional mast cells in patient bone marrow biopsies. D816V KIT suppression of the pro-apoptotic BH3-only death regulator BIM was observed in neoplastic mast cells. Bim has been shown to act as a tumor suppressor in a variety of myeloid neoplasms. Evidence to support mutant Kit signaling as a mechanism driving malignant mast cell proliferation is supported by the finding of high expression levels of microphthalmia-associated transcription factor (MITF).[7] Investigators have shown that MITF expression is upregulated by Kit signaling in primary SM cells and cell lines through downregulation of repressive miRNAs (miR-539 and miR-381). The critical gene targets of MITF responsible for mast cell proliferation remain unclear. Of interest, high MITF levels are not found in all cases of mastocytosis, suggesting that there are likely

other cooperative factors inducing abnormal mast cell proliferation. It is also possible that Kit D816V affects mast cell function; for instance, it has been shown that hematopoietic progenitors and mast cells carrying Kit D816V migrate to SCF to a greater extent.

In a large prospective cohort study of adult patients with SM, disease phenotype and Kit genotype were correlated with age of disease onset. This study of 142 patients with histologically confirmed mastocytosis showed that although genotypic differences were observed, clinical features of adult patients with mastocytosis were the same regardless of whether their disease began in childhood or adulthood. The demonstration of KitD816V in 40% of adult patients with childhood-onset SM would suggest that pediatric patients with Kit mutations have a higher probability of the disease persisting into adulthood.

The bone marrow microenvironment in SM is often altered with increased angiogenesis, osteosclerosis, and variable amounts of fibrosis being observed. Neoplastic mast cells express oncostatin M (OSM), a fibrogenic and angiogenic modulator that appears to be mediated by Kit D816.[8] Ba/F3 cells induced to express Kit D816V produce enhanced levels of OSM mRNA as well as protein product, and HMC-1.2 cells with mutated Kit expressed significantly greater amounts of OSM than did wild-type Kit HMC-1.2 cells. Furthermore, STAT5 knockdown results in inhibition of OSM production in this cell line. Neoplastic mast cells have been shown to express elevated levels of cytoplasmic and nuclear p-STAT5, which has been attributed to Kit D816V.

FIP1L1-PDGFRA

SM patients frequently exhibit eosinophilia (SM-eo), and in at least some cases the eosinophils appear to be derived from the neoplastic clone. A subset of cases with eosinophilia harbor the FIP1L1-PDGFRA oncogene, which results from an interstitial deletion in chromosome 4q12 that removes a segment of DNA involving CHIC2 gene, leading to constitutive activation of the platelet-derived growth factor receptor A. PDGFRA tyrosine kinase activity is uniquely sensitive to inhibition by imatinib mesylate. FIP1L1-PDGFRA cannot be detected with classic cytogenetic methods and its detection requires either the use of fluorescence in situ hybridization or reverse transcriptase polymerase chain reaction. In these patients, FIP1L1-PDGFRA involves mast cells and eosinophils in addition to lymphocytes, suggesting that this disorder originates in a multipotent hematopoietic progenitor cell. The bone marrow mast cell infiltration pattern in these patients is similar to that in the typical SM patients with Kit D816V, in that the mast cells are diffusely distributed, with fewer pathonomonic mast cell clusters. The patients harboring FIP1L1-PDGFRA can be classified as having chronic eosinophilic leukemia (CEL), although at least some cases fulfill the criteria for both systemic mastocytosis and CEL, leading in the past to their classification as systemic mastocytosis, subtype SM-CEL. In the 2008 World Health Organization (WHO) classification of myeloid neoplasms, however, FIP1L1-PDGFRA disease was not considered a type of SM but rather was included in a major new category designated as myeloid and lymphoid neoplasms with eosinophilia and abnormalities of PDGFRA, PDGFRB, and FGFR1. The FIP1L1-PDGFRA fusion and the D816V Kit mutation appear to be mutually exclusive oncogenic events. Gain-of-function Kit and PDGFRA mutations have also been identified in gastrointestinal stromal cell tumors. Intriguingly, in both gastrointestinal stromal cell tumors and mastocytosis patients, Kit and PDGFRA mutations appear to be alternative and mutually exclusive genetic events.

In a murine model of chronic eosinophilic leukemia in which FIP1L1/PDGFRA is expressed in hematopoietic stem cells and IL-5 is over-expressed by T cells, mast cell infiltration of the bone marrow and other organs was increased when compared with control mice transplanted with cells overexpressing IL-5. Intestinal mast cell infiltration in the mouse was diminished by administration of neutralizing C-KIT antibody, suggesting synergy between SCF-activated Kit signaling with FIP1LI/PDGFRA–induced mastocytosis. Additionally, in vitro studies show that bone marrow–derived mast cells that are forced to express FIP1L1/PDGFRA proliferate and differentiate in the absence of cytokines and that SCF can induce greater migration than control bone marrow mast cells lacking this gene fusion product.

Other Mutations/Polymorphisms

The presence of Kit D816V alone does not explain the remarkable clinical heterogeneity of human mastocytosis. Kit mutations are not consistently detected in some patients, such as those with children who have cutaneous mastocytosis. Also, other mutations, polymorphisms, and/or karyotypic abnormalities have been detected in mastocytosis, which likely influence the disease phenotype regardless of whether these lesions coexist with Kit D816V. Of note, loss-of-function mutations have also been detected in mastocytosis; the dominant-negative Kit E839K mutation and the IL-4 receptor alpha chain polymorphism Q576R, which are thought to limit mast cell growth and differentiation, are both associated with relatively limited forms of mastocytosis.

Recently, a growing number of overlapping novel mutations have been identified in MPNs. Although the clinical significance of these individual mutations remains unclear, they reveal a complex molecular pathogenesis underlying MPN disorders. Fourteen different mutations involving the TET2 (TET oncogene family member 2) gene located on chromosome 4q24 have been documented in 29% of bone marrow samples from SM patients. Of interest, none of the FIP1L1-PDGFRA–associated SM cases were found to have TET2 mutations. A statistically significant association between the presence of TET2 mutations and monocytosis and female sex was seen. The presence of TET2 mutations did segregate with Kit-D816V, was found in all SM subgroups, and did not influence survival in nonindolent SM.

RAS proteins are membrane-associated GTPases integral for intracellular signaling mediating cell proliferation, differentiation, and survival. Recently, activating NRAS mutations have been identified in 2 of 8 patients tested with advanced mastocytosis but not found in patients with indolent disease.[9] Some data suggest that the acquisition of NRAS mutations preceded Kit mutations.

The interleukin-13 (IL-13) promoter gene polymorphism 1112c/T has also been associated with SM and not cutaneous mastocytosis (CM) and is correlated with elevated serum levels of tryptase and adult onset of SM. Higher levels of IL-13 have been documented in SM patients, and neoplastic MC cells have been shown to express the IL-13 receptor and to proliferate to a greater degree in the presence of IL-13.

Fusion of the lymphoma-related oncoprotein nucleophosmin (NPM) with anaplastic lymphoma kinase (ALK) results in the NPM-ALK fusion gene. This gene, when expressed in a murine transplant model in lethally irradiated IL-9 transgenic mice, results not only in the formation of lymphoma, but in an SM-like disease with atypical multifocal dense MC-infiltrates in visceral organs. Neither IL-9 expression nor NPM-ALK alone was sufficient to produce the histopathologic findings of SM in these mice; both were required to act in concert to cause a mastocytosis-like disease. It is possible that the downstream signaling pathways that are activated by NPM-ALK tyrosine kinase are shared with Kit, serving to regulate growth and survival of neoplastic MCs.

Classification

The classification of disorders characterized by SM has evolved over the years; the first recognition of cutaneous mast cell disease came from Unna's observation in 1887 that the lesions characteristic of urticaria pigmentosa (UP) lesions were histologically composed of mast cell infiltrates. Although the systemic nature of mastocytosis had been alluded to by Sézary and others in the early 1900s, systemic mast cell infiltrates were first histologically demonstrated by Ellis in

1949. Subsequently, a dichotomous view prevailed, wherein benign mastocytosis was separated from malignant mastocytosis, based on the presence or absence of several clinical features, including UP and organomegaly, particular cytologic and cytochemical features of bone marrow mast cells, as well as the clinical course. Based on the recognition that not all patients classified as having benign mastocytosis have a favorable outcome, and that malignant mastocytosis was composed of relatively distinct clinicopathologic entities, updated classifications have been proposed, generally with four or five subgroups. Updated diagnostic criteria and consensus classification for mastocytosis were proposed and adopted by WHO in 2008.[10] This classification system incorporates advances in our understanding of mastocytosis, including the role of C-KIT mutations, aberrant expression of cell surface immunophenotypic markers on neoplastic mast cells, and mast cell mediators as surrogate measures of mast cell number and/or function.

The current WHO classification identifies seven mastocytosis variants (Table 71-1): cutaneous mastocytosis (CM), indolent systemic mastocytosis (ISM), systemic mastocytosis with an associated clonal hematologic non–mast cell lineage disease (SM-AHNMD), aggressive systemic mastocytosis (ASM), mast cell leukemia (MCL), mast cell sarcoma (MCS), and extracutaneous mastocytoma (EM). ISM can also be further subdivided into two subvariants, isolated bone marrow mastocytosis (BMM) and smoldering systemic mastocytosis (SSM). In addition, two relatively rare variants of mastocytosis with characteristic clinicopathologic features have also been described: well-differentiated systemic mastocytosis (WDSM) and systemic mastocytosis without skin involvement associated with recurrent anaphylaxis (SM-ana). The WHO classification of mastocytosis mandates a number of investigations to define the exact subtype of disease. Identification of B findings (Table 71-2) alone, such as more than 30% mast cells in the bone marrow or serum tryptase greater than 200 ng/mL, is indicative of a high systemic mast cell burden (e.g., smoldering SM), whereas the additional presence of C findings (Table 71-3), such as cytopenias, pathologic fractures, hypersplenism, and so on, indicates impaired organ function directly attributable to mast cell infiltration and the presence of aggressive disease (e.g., ASM). A large retrospective study of 342 individuals with SM seen at the Mayo Clinic observed over approximately 30 years determined the distribution of the incidence of ISM, SM-AHNMD, ASM, and MCL as 46%, 40%, 12%, and 1%, respectively.

Table 71-1 World Health Organization Variants of Mastocytosis

1. Cutaneous mastocytosis (CM)
 a. Maculopapular CM
 b. Diffuse CM
 c. Mastocytoma of skin
2. Indolent systemic mastocytosis (ISM)
 a. Smoldering systemic mastocytosis (SSM)
 b. Isolated bone marrow mastocytosis
3. Systemic mastocytosis with an associated clonal hematologic non–mast cell lineage disease (SM-AHNMD)
 a. SM-MDS
 b. SM-MPD
 c. SM-CEL
 d. SM-CMML
 e. SM-NHL
4. Aggressive systemic mastocytosis (ASM)
 With eosinophilia (SM-eo)
5. Mast cell leukemia (MCL)
 Aleukemic MCL
6. Mast cell sarcoma (MCS)
7. Extracutaneous mastocytoma (EM)

CEL, Chronic eosinophilic leukemia; *CMML*, chronic myelomonocytic leukemia; *MDS*, myelodysplastic syndrome; *MPD*, myeloproliferative disorder; *NHL*, non–Hodgkin lymphoma.

Clinical Manifestations

The clinical manifestations of SM reflect the consequences of either mediator release from mast cells or infiltration of mast cells into virtually any tissue. Mast cell disease has a varied clinical presentation with symptoms that may be broadly grouped as follows:

Skin Rash

Three major forms of cutaneous mastocytosis are recognized by the WHO. The most common is urticaria pigmentosa (also referred to as *maculopapular cutaneous mastocytosis [MPCM]*); the others are diffuse cutaneous mastocytosis and solitary mastocytoma of the skin. The skin lesions are typically yellowish tan to reddish brown macules and may less frequently present as nodules or plaques (Fig. 71-1). The lesions generally involve the extremities, trunk, and abdomen, but spare sun-exposed areas, including the palms, soles, and scalp. The lesions commonly exhibit an urticarial response to mechanical stimulation such as stroking or scratching (Darier sign or dermographic urticaria). Darier sign has been reported rarely in leukemia cutis and cutaneous T-cell lymphomas but is considered pathognomonic for CM. Biopsies of UP/MPCM lesions demonstrate multifocal MC aggregates mainly around blood vessels and around skin appendages in the papillary dermis (Fig. 71-2). An increase in dermal MC, in the absence of typical UP lesions, is not considered diagnostic of CM, given the relatively nonspecific nature of such a finding. Children account for nearly two-thirds of all reported cases of cutaneous mastocytosis, with a majority of cases arising before the age of 2 years. In contrast, most adult MCD patients with UP/MPCM present with systemic disease (often indolent) that is most commonly revealed by a bone marrow biopsy done as part of the diagnostic workup. CM is often associated with systemic symptoms related to the release of mast cell mediators. Flushing, itching, blistering, diarrhea, abdominal pain, vomiting, hypotension, headache, and bone pain are frequent accompanying symptoms. The course of pediatric mast cell disease is usually benign and transient. Skin lesions have a tendency to undergo partial or complete remission during puberty in the majority of children.

Table 71-2 "B" Findings: Indication of High Mast Cell Burden

1. Infiltration grade (mast cells) greater than 30% in bone marrow in histology and serum total tryptase levels greater than 200 ng/mL
2. Hypercellular marrow with loss of fat cells, discrete signs of dysmyelopoiesis without substantial cytopenias, or WHO criteria for an MDS or MPD
3. Organomegaly: palpable hepatomegaly, splenomegaly, or lymphadenopathy (on CT or ultrasound) greater than 2 cm without impaired organ function

MDS, myelodysplastic syndrome; *MPD*, myeloproliferative disorder; *WHO*, World Health Organization.

Table 71-3 "C" Findings: Indication of Impaired Organ Function Attributable to Mast Cell Infiltration

1. Cytopenia(s): Absolute neutrophil count <1000/μL or hemoglobin <10 g/dL or platelets <100,000/μL
2. Hepatomegaly with ascites and impaired liver function
3. Palpable splenomegaly with hypersplenism
4. Malabsorption with hypoalbuminemia and weight loss
5. Skeletal lesions: large-sized osteolysis or severe osteoporosis causing pathologic fractures
6. Life-threatening organopathy in other organ systems that is definitively caused by an infiltration of the tissue by neoplastic mast cells

Symptoms Related to Mast Cell Degranulation

Most adult patients in this category have a low systemic mast cell burden, commonly exhibit CM lesions, and generally have indolent disease. Presenting symptoms include pruritus, urticaria, angioedema, flushing, bronchoconstriction, neuropsychiatric manifestations, and hypotension.[11] Aggregation of high affinity receptors for IgE on mast cell surfaces elicits the release of preformed granule-associated inflammatory mediators that lead to mediator-related symptoms. Gastrointestinal features such as nausea, vomiting, abdominal pain, diarrhea, and malabsorption may be prominent in some patients. GI symptoms occur in 60% to 80% of patients. Histamine receptor stimulation increases gastric acid production, which may cause peptic ulcer disease with potential morbidity from a bleeding peptic ulcer and/or perforation. Peptic ulcer disease has been reported in about 25% of cases. Presyncope, episodic vascular collapse, and sudden death represent the more dramatic clinical presentations of mast cell mediator release.

Figure 71-1 URTICARIA PIGMENTOSA LESIONS IN A PATIENT WITH CUTANEOUS MASTOCYTOSIS.

Headaches are known to be a significant contributor to SM-related disability and include migraine and tension-type headaches. Primary headache syndromes usually parallel mast cell activation and concurrent mast cell degranulation symptoms (i.e., pruritus and rhinorrhea).[12] Mast cells have been identified in the dura mater, in association with connective tissue, neural, and vascular components in patients with SM. Primary cough headaches and migraines with a high incidence of auras appear to be particularly common associated neurologic manifestations of SM.

Severe life-threatening anaphylaxis can be triggered by the release of MC-derived vasoactive mediators. The actual trigger or provoker of MC degranulation is not always readily identifiable. In approximately 3% of cases of mastocytosis, severe life-threatening anaphylaxis can occur.[13] Prolonged hypotension following anaphylaxis and cerebral hypoxia have been identified as the major causes for disability and death in these cases. Neither the subtype of mast cell disease nor the degree of mast cell burden appears to correlate with the severity or frequency of severe anaphylaxis. Severe life-threatening or disabling anaphylaxis to Hymenoptera venom is associated with SM. A primary cause of disability is cerebral hypoxia following anaphylactic shock, which is frequently seen after bee or wasp stings in patients with a high burden of mast cells. Anaphylactic symptoms are more common in males who have mastocytosis with elevated IgE levels.

Musculoskeletal Symptoms

Patients may have indolent or aggressive disease and present with poorly localized bone pain, diffuse osteoporosis or osteopenia, myalgias, arthralgias, pathologic fractures, skeletal deformities, and/or compression radiculopathies. In the absence of typical cutaneous lesions (i.e., UP/MPCM) or mast cell–mediator–release symptoms, the diagnosis of SM may prove challenging, and diagnosis is frequently delayed in this setting. In such cases, SM must be distinguished from other disorders, including osteoporosis, metastatic cancer, Paget disease, and multiple myeloma. Vertebral osteoporosis

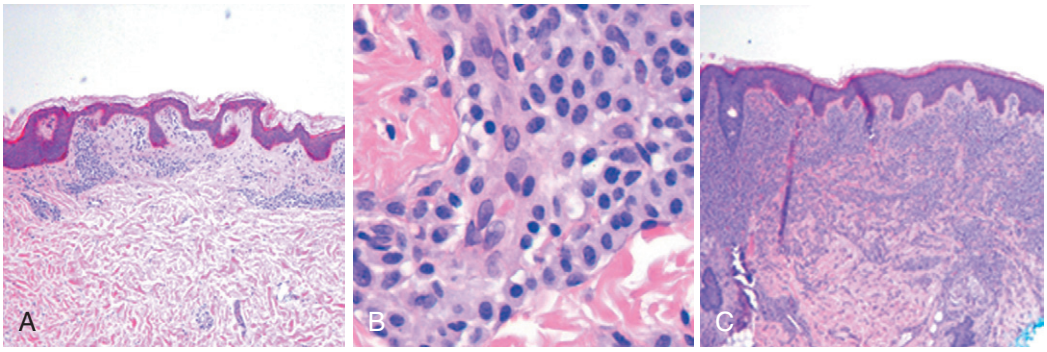

Figure 71-2 CUTANEOUS MASTOCYTOSIS. A skin biopsy of urticaria pigmentosa or maculopapular mastocytosis shows multiple focal aggregates of mast cells around blood vessels or skin appendages in the papillary dermis (**A**). The mast cells are plump with abundant cytoplasm and typically accumulate around vessels (**B,** *center*). In solitary mastocytoma of the skin or in diffuse cutaneous mastocytosis, the mast cell infiltrate is more extensive as it infiltrates the papillary and reticular dermis and may even extend into the subcutaneous tissues. The mast cells are bland and without cytologic atypia. In these disorders, there should be no evidence of systemic involvement. Evidence of systemic disease would indicate systemic mastocytosis.

and fractures are frequently seen in ISM; thus spine radiographs and bone densitometric assays should routinely be performed in this patient population.

Symptoms Related to Organomegaly/Organopathy

SM patients in this category are generally older, do not have CM lesions, frequently exhibit organomegaly and mast cell atypia (i.e., high-grade morphology), and commonly experience an aggressive disease course. Organ infiltration by neoplastic mast cells may lead to hepatomegaly (with or without liver dysfunction and ascites), splenomegaly (with or without hypersplenism), lymphadenopathy, large osteolytic lesions (with or without pathologic fractures), and infiltration of the small intestine with malabsorption, hypoalbuminemia, and weight loss. Extensive marrow involvement may result in anemia and eventually leads to pancytopenia.

Laboratory Manifestations

The diagnosis of SM is based on the identification of abnormal mast cells by morphologic, immunophenotypic, and/or genetic (molecular) criteria in various organs.

Bone Marrow Histology

The mast cell burden in normal bone marrow is very low (<0.1%) and increases significantly in SM patients. Increased numbers of tissue mast cells can appear in the marrow or in a variety of other organs in response to a variety of allergic reactions, autoimmune disorders, or non–mast cell cancers. Mast cells can be increased in such diverse disorders as eosinophilic gastritis, chronic gastrointestinal neoplasms, parasitic infections, inflammatory bowel disease, atopic dermatitis, asthma, and allergic rhinitis. Hodgkin disease, for instance, is frequently associated with mast cell infiltration that correlates directly with disease severity; yet the mechanisms underlying this relationship remain unclear. In Hodgkin disease, mast cells promote the growth of tumors by modifying the tumor microenvironment. The microenvironments of many other tumors, which are composed of stromal cells such as endothelial cells, fibroblasts, and immune cells, provide a supportive niche that promotes the growth and invasion of tumors. Mast cells accumulate in the microenvironment of these tumors, leading to significant organ involvement, and their presence is associated with poor prognosis. These reactive forms of mastocytosis must be distinguished from the various forms of SM. Reactive mast cells are small with round, centrally located nuclei. The diagnosis of SM is most frequently established by histologic and immunohistochemical examination of bone marrow aspirate and biopsy specimens. The bone marrow is virtually always involved in adults and shows characteristic histologic features; in contrast, histologic criteria for organ involvement beyond the marrow have not been clearly defined or widely accepted to date. Furthermore, a bone marrow examination allows determination of whether an associated clonal non–mast cell lineage hematologic disorder is present. The pathognomonic lesion is characterized by the presence of multifocal, dense mast cell aggregates, frequently in perivascular and/or paratrabecular locations (Fig. 71-3). These aggregates may be relatively monomorphic (composed mainly of fusiform mast cells) or polymorphic, with mast cells admixed with lymphocytes, eosinophils, neutrophils, histiocytes, endothelial cells, and fibroblasts. Eosinophils are commonly observed at the periphery of mast cell aggregates (often focally), but increased numbers of eosinophils may also be seen in areas not involved by mast cells. Although irregular trabecular thickening is commonly noted, particularly when mast cell aggregates abut

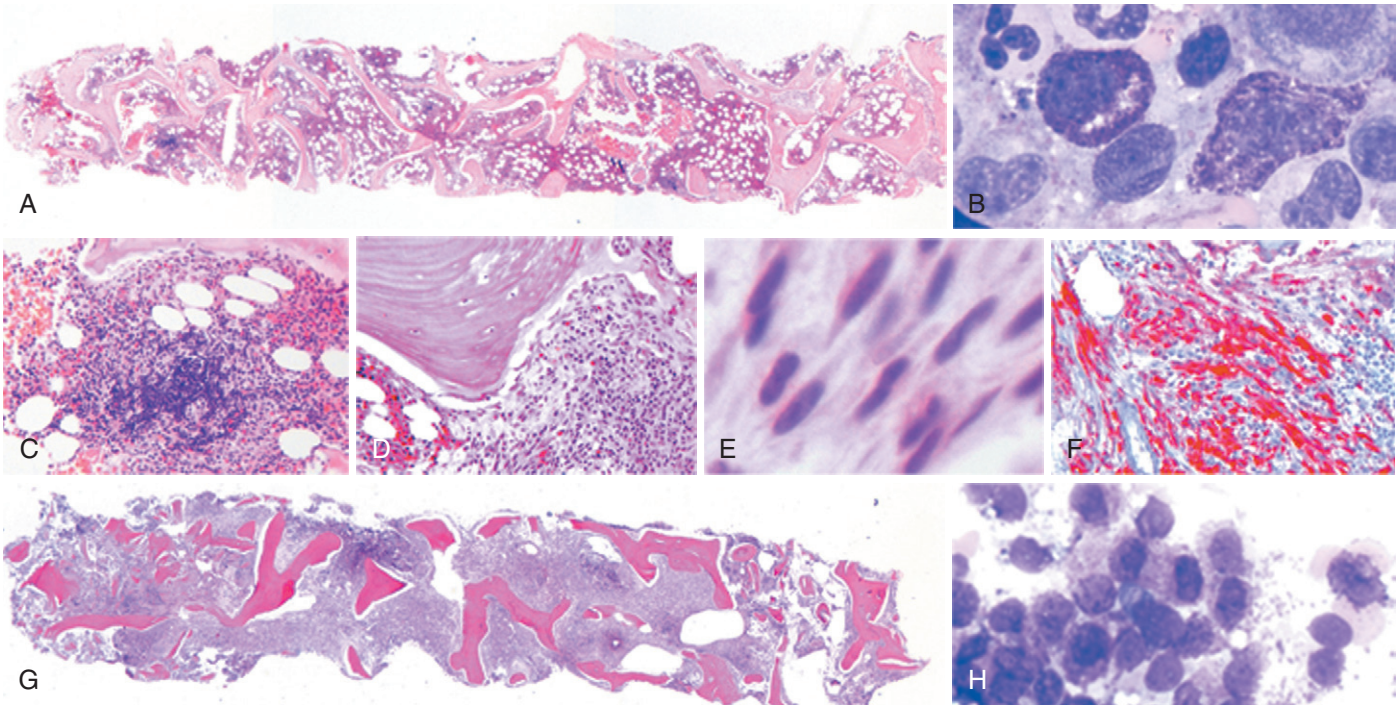

Figure 71-3 SYSTEMIC MASTOCYTOSIS. Bone marrow biopsy (**A**) shows multiple small foci of involvement by systemic mast cell disease. The aspirate (**B**) contained only scattered mast cells (mast cells do not aspirate well). The involved areas on the biopsy include nodules of mast cells (**C**, and *far left bottom* in **A**) with central accumulations of lymphocytes resulting in the so-called bull's eye pattern, and paratrabecular foci (**D**, and *far right bottom* in **A**) along thickened bone. The latter can easily mimic lymphoma in the bone marrow, which can also exhibit a paratrabecular pattern of infiltration. High power of the mast cell involvement (**E**) illustrates the typical fusiform or spindled appearance of the mast cells. A mast cell tryptase immunohistochemical stain (**F**) is quite useful diagnostically. CD117 and CD25 were also positive. A second case (**G**) illustrates extensive involvement by an aggressive systemic mastocytosis. Note the extensive replacement of the marrow space and the marked osteosclerosis. Numerous mast cells are seen on the aspirate (**H**).

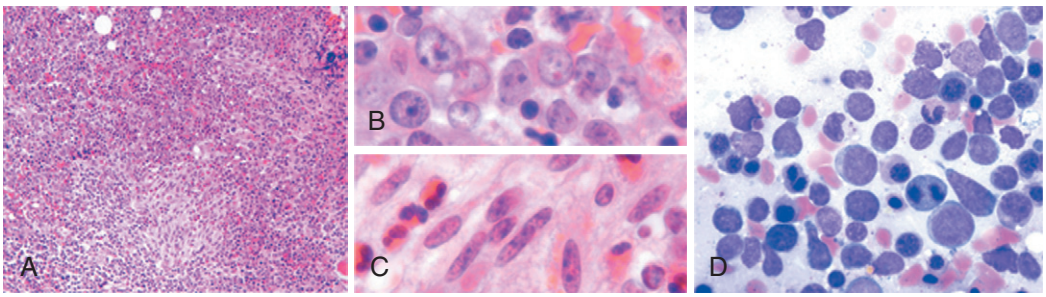

Figure 71-4 SYSTEMIC MASTOCYTOSIS WITH AN ASSOCIATED CLONAL HEMATOLOGIC NON–MAST CELL DISORDER. Low-power depiction of bone marrow (**A**) from a 57-year-old female with systemic mastocytosis associated with acute myeloid leukemia. A focus of mast cells is present (**A**, *bottom center*) in the hypercellular marrow. High-power depictions of the same area (**B**) demonstrate increased immature cells, including blasts, and the mast cell focus (**C**) composed of fusiform mast cells associated with eosinophils. The mast cells were shown to be mast cell tryptase–positive, $CD25^+$ and $CD117^+$. The marrow aspirate (**D**) illustrates increased myeloblasts associated with multilineage dysplasia.

the trabeculae, other cases may be characterized by a marked thinning of bone marrow trabeculae and osteopenia. Mast cell infiltrates are commonly associated with a dense network of reticulin fibers; in cases with diffuse marrow infiltration by monomorphous, spindled mast cells that resemble fibroblasts, a diagnosis of primary myelofibrosis may be erroneously made, especially when accompanied with a decrease in normal hematopoietic elements.

Three distinct patterns of bone marrow mast cell infiltration have been described in SM.[14] The most common, type I pattern, is frequently associated with UP and indolent disease; the mast cells are focally increased (generally 10% to 30% of marrow cellularity), with normal distribution of fat and other hematopoietic elements in the uninvolved marrow space. A spectrum of atypical morphologic features, including cell spindling, cytoplasmic hypogranulation or uneven granule distribution, cytoplasmic processes, and nuclear abnormalities, is seen in mast cells from these patients. Much less commonly, the mast cells may appear relatively normal. In contrast, the type II pattern consists of a significant increase in granulopoiesis in areas not involved by mast cells, as may be seen in ASM patients; some of these cases meet WHO criteria for diagnosis of a clonal non–mast cell lineage hematologic disorder associated with mastocytosis (SM-AHNMD) (Fig. 71-4). The latter (i.e., SM-AHNMD) is the second most common mastocytosis category (more common than ASM) and may account for up to one-third of SM patients. The coexistence of these two entities (i.e., mastocytosis and non–mast cell neoplasm) likely reflects their origin in a common multipotent hematopoietic progenitor cell, although in rare cases the two may develop independently. The diagnosis of SM-AHNMD is established by WHO criteria, for both the mastocytosis and non–mast cell neoplasm components (Table 71-4). In most SM-AHNMD cases, a diagnosis of mastocytosis is made incidentally, usually after an examination of bone marrow for evaluation of the non–mast cell hematologic disorder. In such cases, it is difficult to ascertain whether mastocytosis existed before the onset of the non–mast cell disorder, although some patients provide historical clues (time of onset of UP lesions and/or symptoms of mast cell degranulation) in this regard. In most cases, the non–mast cell neoplasm tends to clinically overshadow the mastocytosis component, thereby reflecting its more aggressive biologic nature. The most frequent non–mast cell disorders associated with mastocytosis are the chronic myeloproliferative neoplasms (except BCR-ABL–positive CML), AML, and MDS.[15] The recognition that chronic myelomonocytic leukemia (CMML), a hybrid myeloproliferative–myelodysplastic disorder, is commonly associated with mastocytosis supports the contention that dysmyelopoiesis is a prominent feature of SM. In some cases, the bone marrow mast cell involvement may be obscured by the non–mast cell neoplasm if only conventional stains are employed (vide infra). In this regard, mast cell infiltrates are more easily identified within sheets of monotonous blasts in AML than within the polymorphic infiltrates seen in myeloproliferative or myelodysplastic disorders. Patient characteristics associated with type II pattern include older age, absence of UP lesions, organomegaly, anemia, eosinophilia, greater than 10% morphologically atypical mast cells in the bone marrow, elevated serum tryptase level, and a rapid clinical course. Type III pattern is characterized by diffuse marrow infiltration with atypical mast cells of high-grade morphology, frequently with circulating mast cells. MCL (Fig. 71-5) is characterized by increased numbers of mast cells in bone marrow (>20% in aspirate smear) and peripheral blood (>10%), with associated bone marrow failure manifested as peripheral cytopenias. The mast cells are immature, sometimes blastic, and often have sparse metachromatic granules, and hence may be missed

Table 71-4 World Health Organization Diagnostic Criteria for Variants for Systemic Mastocytosis

1. Indolent systemic mastocytosis (ISM): Meets criteria for SM. No "B" or "C" findings. No evidence of associated clonal hematologic malignancy/disorder. In this variant, the mast cell burden is low; skin lesions are almost invariably present.
 - *Bone marrow mastocytosis:* As above, with bone marrow involvement, but no skin lesions.
 - *Smoldering systemic mastocytosis:* As above, but with two or more "B" findings and no "C" findings.
2. Systemic mastocytosis with associated clonal hematologic non–mast cell lineage disease (SM-AHNMD): Meets criteria for SM and criteria for an associated, clonal hematologic non–mast cell lineage disease (MDS, CMPD, AML, lymphoma, or other hematologic neoplasm that meets the criteria for a distinct entity in the WHO classification).
3. Aggressive systemic mastocytosis (ASM): Meets criteria for SM. One or more "C" findings. No associated clonal hematologic malignancy/disorder. No evidence of mast cell leukemia.
 - *Lymphadenopathic mastocytosis with eosinophilia:* Progressive lymphadenopathy with peripheral blood eosinophilia, often with extensive bony involvement, and hepatosplenomegaly, but usually without skin lesions. Cases with rearrangement of PDGFRA are excluded.
4. Mast cell leukemia: Meets criteria for SM. Bone marrow biopsy shows diffuse infiltration, usually interstitial pattern, by atypical, immature mast cells. Bone marrow aspirate smears show 20% or more mast cells. Mast cells account for 10% or more of peripheral blood white cells.
 - *Aleukaemic mast cell leukemia: A rare variant.* As above, but <10% of WBCs are mast cells. Usually without skin lesions.
5. Mast cell sarcoma: Unifocal mast cell tumor. No evidence of SM. No skin lesions. Destructive growth pattern. High-grade cytology.
6. Extracutaneous mastocytoma: Unifocal mast cell tumor. No evidence of SM. No skin lesions. Nondestructive growth pattern. Low-grade cytology.

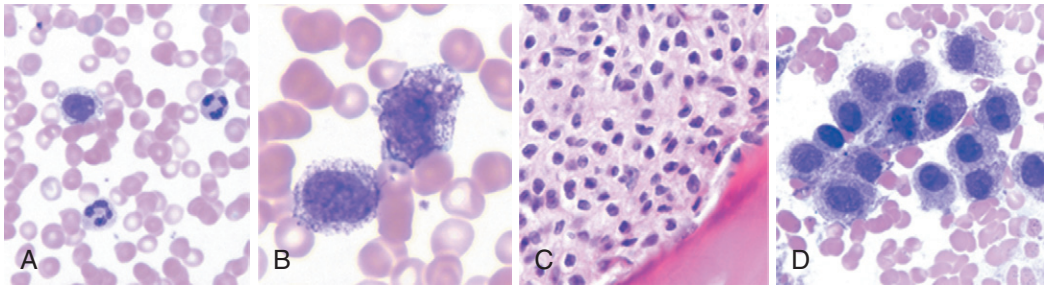

Figure 71-5 MAST CELL LEUKEMIA. Low-power depiction of peripheral blood (**A**), showing two granulocytes and a single immature mast cell with sparse metachromatic granules. Two additional circulating mast cells are also illustrated (**B**). The marrow biopsy was packed with mast cells (**C**). Note the cells are held apart from one another because of their abundant cytoplasm. A similar pattern of infiltration is seen in hairy cell leukemia and in acute promyelocytic leukemia. The aspirate (**D**) shows sheets of immature and hypogranular mast cells.

on routine staining unless tryptase and/or immunophenotyping studies are performed. Rare aleukemic variants of MCL have also been described. Rarely, patients may present with increased numbers of metachromatically granulated, primitive, blast-like cells. In such cases, differentiating MCL from tryptase-positive and/or Kit D816V–positive AML or acute basophilic leukemia is a diagnostic challenge in the absence of well-defined criteria. The aforementioned histologic patterns appear to be relevant for assessing patient prognosis. In one study, mastocytosis patients with a type I pattern (ISM) had an actuarial 5-year survival rate of 75%, compared with 17% and 0% for patients with type II (ASM or SM-AHNMD) and type III (MCL) patterns, respectively. Although mast cell cytologic atypia (large, irregularly shaped nuclei, increased mitotic activity, decreased numbers of metachromatic granules, etc.) has been historically proposed by some authors as criteria for aggressive mastocytosis, such proposals have not been broadly accepted or implemented in routine practice.

In general, mast cells may not be readily recognized by standard staining procedures such as Giemsa, toluidine blue, or naphthol AS-D chloroacetate esterase (Leder stain), particularly when associated with significant hypogranulation or with abnormal nuclear morphology, and may be confused with a variety of other cells that include fibroblasts, histiocytes, hairy cells, and monocytes, particularly in polymorphic bone marrow mast cell aggregates. Furthermore, the metachromatic staining properties of mast cells may be significantly diminished or lost with conventional tissue processing, particularly decalcification with acidic solutions that is necessary for sectioning of paraffin-embedded bone marrow tissue. Among the immunohistochemical markers, staining for tryptase is considered the most sensitive, being able to detect even small-sized mast cell infiltrates (i.e., composed of 10 to 15 cells) (see Fig. 71-3).[16] Given that virtually all mast cells (regardless of their stage of maturation, activation status, or tissue site) express tryptase, staining for this marker detects even those infiltrates that are primarily composed of immature, poorly granulated mast cells. Tryptase immunostaining is particularly useful for assessing the diffuse pattern of mast cell infiltration, particularly when the cells are loosely distributed, in contrast to discrete mast cell aggregates. It must be emphasized that neither tryptase nor other immunohistochemical markers such as chymase, Kit/CD117, or CD68 can distinguish between normal and neoplastic mast cells. Also, abnormal basophils seen in some cases of acute and chronic basophilic leukemia, as well as in chronic myeloid leukemia, and blasts in some AML cases may be tryptase positive and may prove difficult to distinguish from mast cells. In contrast, immunohistochemical detection of aberrant CD25 expression by bone marrow mast cells appears to also be a reliable diagnostic tool in SM, given its ability to detect abnormal mast cells in all subtypes of mastocytosis, including the rare cases with loosely scattered, interstitial mast cells.[17] A unilateral bone marrow biopsy may not be sufficient to exclude low levels (early stages) of mast cell involvement. In a retrospective analysis of 23 mastocytosis patients who underwent bilateral bone marrow biopsies, 4 cases (17%) had unilateral involvement only. Three of the four patients had low serum tryptase levels (<25 ng/mL); hence the diagnosis of SM may not have been established without bilateral biopsies.

Mast Cell Immunophenotyping

As mentioned previously, the qualitative and semiquantitative profiling of cell surface antigens by multiparametric flow cytometry can be extremely useful in distinguishing normal bone marrow mast cells from their pathologic counterparts in SM.[18] Normal mast cells typically express Kit/CD117 and FcεRI, and their typical profile is $CD117^{++}$/Fc $RI^{+}/CD34^{-}/CD38^{-}/CD33^{+}/CD45^{+}/CD11c^{+}/CD71^{+}$. These cells do not express certain myeloid markers (CD14 and CD15) or lymphoid lineage markers, except CD22. Neoplastic mast cells typically express CD25 and/or CD2, and the abnormal expression of at least one of these two antigens is considered a minor criterion toward the diagnosis of SM, according to the WHO. Overexpression of CD63, CD69, CD58, CD33, and CD11c by neoplastic mast cell is also observed. In general, the detection of CD25 on mast cells, by either flow cytometry or immunohistochemistry, appears to be the more reliable marker (relative to CD2), although some authors have noted significant variation in the percentage of CD2-positive cases by flow cytometry depending on the specific antibody-fluorochrome conjugate used. Consistent with flow cytometry data, it has been reported that screening for CD2 expression by immunohistochemistry may have relatively low diagnostic value because a significant proportion of cases stain negative, and CD2 expression on bone marrow mast cells is generally weak in the cases that are positive. In a large study conducted by REMA (Spanish network on mastocytosis), the sensitivity and specificity of CD2 versus CD25 expression in the diagnosis of SM was evaluated in 886 bone marrow and 153 non–bone marrow extracutaneous tissue samples.[19] The inclusion of CD2 did not improve the sensitivity and decreased the specificity of this test when compared with evaluating CD25 expression alone (sensitivity 100%, specificity 99.2%). This group proposes future modification of the WHO diagnostic criteria to replace the minor criterion of CD2 and/or CD25 by bone marrow, peripheral blood, or other extracutaneous tissue mast cells to a major criterion of exclusive CD25 expression.

Interval monitoring of CD25 expression on bone marrow mast cells may represent one approach for assessing presence of residual disease in patients undergoing mast cell–cytoreductive therapy, generally for the aggressive forms of mastocytosis. Other aberrant immunophenotypic features of neoplastic mast cells include abnormally high expression of complement-related markers such as CD11c, CD35, CD59, and CD88, as well as increased expression of the CD69 early-activation antigen, and the CD63 lysosomal-associated protein. Three distinct immunophenotypic patterns were determined by flow cytometry analysis in 123 SM patients: an immature

immunophenotype present in ASM ($CD25^+/CD2^-/CD63^+/CD69^+$) and MCL ($CD25^+/CD2^-/CD63^-/CD69^-$) and a mature activated or resting phenotype ($CD25^-/CD2^-$). Each pattern was associated with distinct genetic markers and clinical behavior.

Peripheral blood $CD34^-$ cells, which express C-KIT when isolated and cultured, give rise to mature mast cells, indicating that this population represents a mast cell precursor. The number of peripheral blood $CD34^-$ $C\text{-}KIT^+$ cells in SM patients is significantly higher than that in normal donors and correlates with the severity of mastocytosis (higher in ASM and SM-AHNMD compared with ISM) and has been used to determine disease severity, detect early relapse, and assess treatment response.[20]

Serum Tryptase Measurements

The measurement of tryptase (a mast cell enzyme with trypsin-like enzymatic activity) levels in biologic fluids (serum) has proven to be a useful disease-related marker in SM and is included as a minor criterion for diagnosing the condition according to WHO guidelines, provided that certain conditions are satisfied.[10] There are two major forms of mast cell tryptase: alpha (subtypes α_1 and α_2) and beta (subtypes β_1, β_2, and β_3). Mature β_2-tryptase is stored in mast cell secretory granules as an enzymatically active tetramer complexed with proteoglycans and is released only during granule exocytosis, thereby largely reflecting mast cell activation.[21] In contrast, the precursor forms of both α-tryptase and β-tryptase are constitutively secreted by mast cells, and the combined total serum levels (including precursor and mature tryptase forms) are thought to correlate with systemic mast cell number, albeit with effects related to tryptase haplotype and gender. The commercially available fluoroimmunoenzymatic assay measures total tryptase levels; in healthy individuals, levels range from 1 to 15 ng/mL, whereas in most patients with SM, total serum tryptase levels exceed 20 ng/mL. In cases of suspected mastocytosis, it is important that serum tryptase levels be interpreted in the appropriate context. Elevated levels of serum tryptase have been documented in patients with non–mast cell myeloid malignancies, including acute myeloid leukemia (AML), myelodysplastic syndrome (MDS), and chronic myeloid leukemia (CML), which mandates exclusion of such non–mast cell myeloid disorders before reaching a diagnosis of SM. Furthermore, levels of serum tryptase, particularly mature β-tryptase, are frequently elevated in association with anaphylaxis or a severe allergic reaction. Total tryptase levels may also be useful for monitoring treatment response in mastocytosis patients; interpretation of levels, however, must take into account other clinical/laboratory data, given the potential inherent variability of tryptase levels, as well as other possible confounding effects, such as administration of radiocontrast agents or narcotics, that may lead to mast cell degranulation.

Recently, REMA created a simple clinical score based on age, sex, serum baseline tryptase level, the presence of presyncope/syncope, and the presence of pruritus, hives, or angioedema to predict bone marrow mast cell clonality. In a prospective study, the clinical utility of the REMA score was validated in 158 patients with MCAS in the absence of MIS to predict not only bone marrow mast cell clonality but also the diagnosis of SM by WHO criteria (before a bone marrow study).[22] The REMA score was found to be more sensitive than the serum baseline tryptase level of >20 ng/L alone in predicting a diagnosis of SM.

Molecular Studies

In patients with mastocytosis, molecular studies are clearly important diagnostically; moreover, these studies are becoming increasingly important from a therapeutic standpoint as well. Recent studies underscore the high prevalence of the Kit D816V gain-of-function mutation in mastocytosis patients, with high correlation between mutation detection and the proportion of lesional/clonal cells in the sample, as well as the sensitivity of the screening method employed. Molecular detection of Kit mutations are preferably performed on fresh bone marrow aspirate, clot sections, or bone marrow biopsy specimens that are fixed in formalin and decalcified in EDTA. The likelihood of detecting the mutation in peripheral blood mononuclear cells in a case of indolent mastocytosis (with low probability of circulating clonal cells), using a low-sensitivity screening test (e.g., DNA sequencing), is quite low. The sensitivity of detection may be enhanced by enriching lesional mast cells or other clonal cell populations (e.g., neutrophils or eosinophils) by laser-capture microdissection or magnetic bead-based cell sorting, respectively. Furthermore, use of higher-sensitivity methods, including allele-specific PCR or PCR with peptide nucleic acid (PNA) probes, to clamp the wild-type allele combined with mutant allele detection with hybridization probes dramatically enhances the probability of mutation detection in bulk cells (sensitivity $=10^{-3}$). Using a higher sensitivity method, the D816V mutation has been detected in virtually all patients with ISM or ASM (93%), but less frequently in patients with WDSM (vide infra) (29%). Kit mutations other than D816V (e.g., I817V, VI815-816) were rarely detected (<3%). Notably, most mastocytosis patients with poor prognosis harbored Kit D816V in two or more bone marrow myeloid cell populations (81%), in contrast to patients with indolent mastocytosis (27%).

WDSM may represent a distinct, albeit genetically heterogeneous, subtype of SM. A subset of WDSM cases carries the F522C germline mutation located in the Kit transmembrane domain. In contrast to other SM subtypes, mast cells in WDSM do not (aberrantly) express either CD2 or CD25 antigens and are mature in appearance.

The FIP1L1-PDGFRA mutation can be detected by either fluorescence in situ hybridization (FISH) or PCR-based assays. Some investigators have suggested that PCR (particularly, nested PCR) is a more reliable screening test for FIP1L1-PDGFRA (relative to FISH) in primary eosinophilia, given the low sensitivity of FISH in some cases. Limitations of PCR-based assays include the possibility of an unusual FIP1L1-PDGFRA transcript, given the heterogeneity of breakpoints with the FIP1L1 locus and other mechanisms (e.g., cryptic splice sites), which may lead to a false-negative test result. Finally, although real-time quantitative PCR assays for monitoring FIP1L1-PDGFRA transcript levels have been described, its precise utility in assessing either depth of response with therapy (i.e., detection of minimal residual disease) or for molecular relapse remains unclear at this time.

Biochemical markers can also be used to predict bone marrow involvement in SM. Serum tryptase and urine N-methylhistamine and N-methylimidazole acetic acid have been shown in a study to have high pretest accuracy in predicting the probability of ISM in a given individual with SM-related symptoms.

Differential Diagnosis

The WHO diagnostic criteria for SM are provided in Table 71-5, and the diagnostic criteria for the diagnosis of the SM variants (including ISM, SM-AHNMD, ASM, MCL, MCS, and EM) are presented in Table 71-4. Because mast cells can be seen in other conditions and the treatment approach to ASM/MCL would differ from that of ISM, it is important that a rigorous clinical and laboratory evaluation be performed on an individual with suspected mast cell disease.

The presence of mast cells in a bone marrow aspirate smear or histologic sections prompts a pathologist to a differential diagnosis that includes not only SM but also acute basophilic leukemia, mast cell hyperplasia, myeloid neoplasms with eosinophilia and PDGFR abnormalities, myelomastocytic leukemia, and tryptase-positive AML. Appreciating mast cell cytology (normal, atypical type I, atypical type II, metachromatic blasts) and the pattern of mast cell infiltration (interstitial, diffuse dense, focal dense, tryptase-positive compact round cell infiltrate of the bone marrow) allows for discrimination among these disease entities, and confirmation of D816V Kit further supports the diagnosis of SM.

Table 71-5 World Health Organization Criteria for Diagnosis* of Systemic Mastocytosis

MAJOR

Multifocal dense infiltrates of mast cells in bone marrow or other extracutaneous organ sections (>15 mast cells aggregating)

MINOR

a. >25% mast cells in tissue sections or bone marrow aspirate smears that are spindle-shaped, immature or have atypical morphology
b. C-KIT point mutation at codon 816V detected in bone marrow, blood, or another extracutaneous organ
c. Expression of CD2 and/or CD25 in neoplastic mast cells
d. Baseline serum tryptase persistently >20 ng/mL (not valid in presence of another non–mast cell clonal disorder)

*Diagnosis of systemic mastocytosis requires three minor criteria *or* the sole major plus minor criteria.

SM should be distinguished from mast cell hyperplasia states or mast cell activation syndromes (MCAS) with or without the morphologic and/or molecular abnormalities that characterize a neoplastic proliferation. MCAS is a heterogeneous group of mast cell–related diseases characterized by episodic symptoms that are attributed to mast cell degranulation, including flushing, lightheadedness, dermatographism, crampy abdominal pain, diarrhea, life-threatening hypotension, and neuropsychiatric symptoms (headache, poor concentration, and memory loss). Heat and consumption of alcohol are known to stimulate mast cell mediator release. This includes signs and symptoms involving the dermis, gastrointestinal track, pulmonary system, musculoskeletal system, cardiovascular system, and nervous system. MCAS identifies a group of patients with unexplained or recurrent anaphylaxis without skin lesions or with diseases that do not meet criteria for the diagnosis of SM. Consideration of this diagnosis requires the elimination of a variety of disorders that can mimic the characteristic symptoms. These disorders include carcinoid syndrome pheochromocytoma, medullary thyroid carcinoma, estrogen or testosterone deficiency, inflammatory bowel syndrome, reactions to environmental stimuli, and allergic reactions. The existence of mast cell activation disorders causing sudden and sometimes life-threatening symptoms has been recognized for many decades, but these cases fail to meet the full diagnostic criteria of a mast cell proliferative disorder such as SM. These patients appear to have a hyperresponsive/hypersensitive mast cell population rather than an expanded mast cell population, and long-term follow-up is indicated. Because of the absence of definitive diagnostic criteria for these types of mast cell diseases, proposed diagnostic criteria have been developed.[23] Table 71-6 shows the proposed criteria for MCAS, which require the ruling out of other primary and secondary causes, documentation of urinary or serum markers of mast cell activation, a decrease in frequency or severity of symptoms with antimediator therapy, and the presence of episodic symptoms consistent with mast cell mediator release that affect two or more organ symptoms. This classification scheme will require validation in prospective multicentered clinical trials. A classification has been proposed that distinguishes secondary MC disorders (allergic diseases, physical urticarias, chronic autoimmune urticaria, or associated chronic inflammatory or neoplastic disorders), primary MC disorders (hypotension with mastocytosis or monoclonal mast cell activation syndrome [MMAS]), and idiopathic MC disorders (anaphylaxis, angioedema, urticaria, MCAS). Monoclonal MCAS is characterized by the demonstration of multifocal mast cell clusters of atypical morphology (spindle-shaped and hypogranulated), mast cell CD25 expression, and/or the presence of C-KIT D816V point mutation.[23] Patients who do not meet these criteria are considered to have an idiopathic MCAS. A useful way to distinguish among SM, MMAS, MCAS, and idiopathic anaphylaxis (IA) is provided in Table 71-7.

A set of clinical and laboratory features that is helpful in distinguishing patients with Kit D816V–positive SM with eosinophilia from individuals with the FIP1L1-PDGFRA–positive myeloid neoplasms with eosinophilia has been created. In the D816V Kit–positive group, gastrointestinal symptoms, urticaria pigmentosa, thrombocytosis, median serum tryptase value, and the presence of dense mast cell aggregates in the bone marrow are more frequently observed as compared with FIP1L1-PDGFRA–positive patients. By contrast, male sex, cardiac and pulmonary symptoms, median peak absolute eosinophil count, the eosinophil-to-tryptase ratio, and elevated serum B_{12} levels were higher or more common in the FIP1L1-PDGFRA–positive group. A scoring system incorporating these clinical and laboratory parameters has been created, which can be helpful in predicting whether patients with peripheral eosinophilia and increased marrow mast cell burden carry the D816V Kit mutation or the FIP1L1-PDGFRA, which is important for developing treatment decisions (Table 71-8).

Table 71-6 Proposed Criteria for the Diagnosis of MCAS0*

1. Episodic symptoms consistent with mast cell mediator release affecting two or more organ systems, evidenced as follows:
 a. Skin: urticaria, angioedema, flushing
 b. Gastrointestinal: nausea, vomiting, diarrhea, abdominal cramping
 c. Cardiovascular: hypotensive syncope or near syncope, tachycardia
 d. Respiratory: wheezing
 e. Naso-ocular: conjunctival injection, pruritus, nasal stuffiness
2. A decrease in the frequency or severity or a resolution of symptoms with antimediator therapy: H_1- and H_2-histamine receptor inverse agonists, antileukotriene medications (cysteinyl leukotriene receptor blockers or 5-lipoxygenase inhibitor), or mast cell stabilizers (cromolyn sodium).
3. Evidence of an increase in a validated urinary or serum marker of mast cell activation: Documentation of an increase of the marker to greater than the patient's baseline value during a symptomatic period on two or more occasions or, if baseline tryptase levels are persistently >15 ng/mL, documentation of an increase of the tryptase level above baseline value on one occasion. Total serum tryptase level is recommended as the marker of choice; less specific (also from basophils) are 24-hour urine histamine metabolites or PGD_2 or its metabolite 11-β-prostaglandin F_2.
4. Rule out primary and secondary causes of mast cell activation and well-defined clinical idiopathic entities.

PGD_2, Prostaglandin D_2.
*MCAS remains, for now, an idiopathic disorder; however, in some cases it could be an early reflection of a monoclonal population of mast cells, in which case it could, with time, meet the criteria for MMAS as one or two minor criteria for mastocytosis are fulfilled.

Prognosis

In a retrospective study of 342 adult patients with SM (46% ISM, 12% ASM, 40% SM-AHNMD, 1% MCL) seen at Mayo Clinic, Kit D816V was detected in 68% of patients (78% ISM, 82% ASM, and 60% SM-AHNMD).[24] Survival was superior in the ISM group and was similar to the age- and sex-matched control population, with leukemic transformation occurring as a rare event. Median survival for SM-AHNMD, ASM, and MCL cases was approximately 2 years, 3.5 years, and 2 months, respectively. Median survival for ISM was more than 16 years and was not reached for the BMM subvariant (Fig. 71-6). Advanced age, weight loss, anemia, thrombocytopenia, hypoalbuminemia, and excess bone marrow blasts were identified by multivariable analysis as independent adverse prognostic factors for survival. This large study validates the prognostic significance of WHO diagnostic categories and further justifies therapeutic intervention with a goal to reduce systemic mast cell burden in patients with ASM, MCL, and ISM with severe anaphylaxis. ISM has a low rate of disease progression, and most patients will enjoy a normal life expectancy.[25] The presence of Kit mutations in mast cells, myeloid and lymphoid cells, and an elevated serum β_2-microglobulin has been

Table 71-7 Comparison of Clinical and Diagnostic Features for SM, MMAS, MCAS, and IA

Features	SM	MMAS	MCAS	IA
Baseline tryptase	>20	Normal or mildly increased	Normal or mildly increased	Normal
C-KIT D816V	+	+	–	–

AEC, Absolute eosinophil count; *TKIs,* tyrosine kinase inhibitors.

shown to be predictive of transformation to more aggressive disease. In a prospective study of patients with ISM, age above 60 years and the development of SM-AHNMD were associated with a poor survival, with a probability of death of 2.2% (+/– 1.3%) and 11% (+/– 5.9%) at 5 and 25 years, respectively.

Treatment

Adults with SM generally seek treatment for one or more of the following disease manifestations: skin rash (e.g., UP), symptoms of mast cell degranulation, and/or symptoms related to skeletal involvement or organomegaly/organopathy from mast cell infiltration. Although the treatment of SM has largely been empirically derived, recent advances in our understanding of the molecular pathogenesis of this condition allows for the identification of specific disease subtypes that are uniquely sensitive (or resistant) to specific therapies. Consequently, in this era of increasingly greater access to molecular testing, it is important that SM patients be molecularly profiled for presence or absence of relevant pathogenetic mutations, to enable optimal therapeutic decisions to be possible. The relative rarity of mastocytosis, its biologic heterogeneity, and (historically) the lack of simple, widely accepted treatment response criteria have hitherto served as barriers to development of

Investigational Therapies for Patients With Systemic Mastocytosis

Response Criteria

In order to standardize evaluation of therapies in systemic mastocytosis (SM), it is essential to have uniform response criteria to compare novel therapeutic approaches. For a comprehensive review of the consensus statements on diagnostics, treatment recommendations, and response criteria in mastocytosis by leading world experts in this field, refer to the published results of the Working Conference on Mastocytosis in 2005 (as reported in the European Journal of Clinical Investigation[28]).

Proposed response criteria for cutaneous mastocytosis (CM) or "mastocytosis in the skin (MIS)" include complete regression, or CR (complete disappearance of affected skin lesions); major regression, or MR (reduction in lesions by >50%); partial regression, or PR (reduction in lesions by 10% to 50%); and no regression, or NR (<10% reduction in cutaneous lesions).

Since tryptase levels tend to reflect the mast cell burden in SM, tryptase can be used as a surrogate marker for measuring response to cytoreductive agents. The added value of using soluble-Kit, soluble-CD25 and histamine as markers of disease response is not known. Proposed response criteria for SM include complete resolution, or CR; major response, or MR (>50% reduction in severity and/or significant decrease in frequency, B → A or C → B); partial response, or PR (10% to 50% reduction in severity, no major decrease in frequency); no response, or NR (<10% reduction, no decrease in frequency); and continuous CR, or CCR (symptom-free interval of at least 2 years following initiation of therapy).

The use of consensus response criteria will better enable a uniformed and agreed-upon standard for comparing the clinical response of various agents with differing mechanisms of action.

Tyrosine Kinase Inhibitors

Dasatinib (BMS354825) is an orally bioavailable thiazolecarboxamide that is structurally unrelated to imatinib. It is a dual Src/ABL kinase inhibitor that is more potent than imatinib, and it demonstrates inhibitory activity against a number of BCR-ABL mutations linked to imatinib resistance in CML, but not T315I. Dasatinib inhibits cell lines harboring Kit WT or Kit D816V at nanomolar concentrations. In contrast to imatinib, dasatinib binds to the ABL and Kit ATP-binding sites regardless of the activation-loop conformation. In a large phase II study with 33 SM patients (28 Kit-D816V–positive) were treated with dasatinib at 70 mg twice daily or 140 mg once daily.[29] The ORR was 33%, 2 Kit wild-type patients achieved a CR for up to 15 months in one case, and 9 patients (including Kit D816V–positive SM) had improvements in disease-related symptoms, including rash, diarrhea, bone pain, headaches, itching, fatigue, shortness of breath, indigestion, and decrease or elimination of anaphylactic reactions. Treatment-related adverse events were similar to those seen in previous studies in Ph+ MPNs. It would appear that despite in vitro Kit-D816V inhibitory activity, dasatinib does not exhibit disease-modifying activity in patients with Kit D816V–positive SM, and it is not clear which subgroup of SM may have the best response to this therapy.

Nilotinib (AMN107) is a more potent small-molecule kinase inhibitor with activity against a number of BCR-ABL mutations linked to imatinib resistance in CML, but not T315I. Nilotinib also has in vitro inhibitory activity against cell lines harboring Kit WT or Kit V560G (juxtamembrane mutant) but has limited activity against Kit D816V (IC_{50} in micromolar range). These data suggest that nilotinib may be a less-than-ideal candidate for treatment of patients with systemic mastocytosis, of whom a majority carry the Kit D816V mutation.

Masitinib (AB1010) is a potent oral multityrosine kinase inhibitor selective for C-KIT and PDGFRα/β, as well as for Lyn and Fyn, which are important regulators of IgE-mediated mast cell degranulation. The drug was not effective in inhibiting Kit D816V–driven mast cell proliferation in vitro. This agent was studied in a proof-of-concept, multicentered, nonrandomized, phase IIa study of 25 patients with indolent SM or CM suffering from disease-related symptoms (pruritus, flushing, depression, and reduced quality of life [QOL]) at dose levels of 3 or 6 mg/kg/day over a 12-week core study period.[20,30] Patients were entered into this study if they were refractory to at least one previous treatment and had involvement of at least one organ, with absent Kit D816V. During the 12-week treatment period masitinib significantly reduced SM-associated symptoms and improved QOL. The authors postulated that the clinical response of masitinib in patients with the D816V mutation may be explained in part to the inhibition of Lyn and Fyn, leading to reduced mast cell degranulation. Drug-related adverse events (edema 44%, nausea 44%, muscle spasms 28%, rash 28%) were observed in 84% of patients and were mostly mild to moderate, occurring within the first 12 weeks, and manageable with symptomatic treatments. A single patient experienced reversible agranulocytosis. Depression has been associated with SM and estimated at a prevalence of approximately 64%; masitinib has been shown to improve depression in 67% of cases in a study of 35 patients with indolent SM. Recently, a single patient with MCL was found to have a previously unidentified mutation in Kit (dup[501-502]) and was successfully treated with masitinib, inducing complete resolution of circulating mast cells, decrease in serum histamine and tryptase, and clinical improvement.

Midostaurin (PKC412) is an N-benzoyl-staurosporine, with inhibitory activity against protein kinase C (PKC), FLT3 (FMS-like tyrosine kinase-3), Kit mutants (D816Yand D816V), vascular endothelial growth factor receptor-2 (VEGFR-2), PDGFR, and fibroblast growth factor receptor (FGFR) tyrosine kinases. PKC412 potently inhibits growth of cell lines harboring Kit D816V, and early data suggest activity in patients with advanced SM. In a phase II study, midostaurin administered to 26 patients with SM (4 ASM, 14 SM-CMML, 3 SM-MDS, 1 SM-MDS/MPN, 4 MCL) at a dose of 100 mg twice daily achieved a major response rate of 38%, which included normalization of hypoalbuminemia, improvement in anemia/thrombocytopenia, resolution of transaminitis, improvement in pleural effusions and ascites, and restoration of weight. A patient with MCL had a near complete response. The most common side effects noted were nausea, vomiting, diarrhea, and fatigue. A phase III trial of midostaurin is currently being pursued; the results of this trial are eagerly awaited to determine the true potential of this drug in treating SM patients.

Based on in vitro studies demonstrating that midostaurin could inhibit D816V Kit–transformed Ba/F3 cell growth, a single patient with MCL and an associated myelodysplastic syndrome (MDS)/myeloproliferative neoplasm [MPN]) was treated with midostaurin and obtained a partial response. The patient had resolution of liver function abnormalities, reduction in peripheral blood mast cell percentage, serum histamine level, and decrease in Kit phosphorylation and D816V Kit–mutation frequency; however, the patient died after 3 months of therapy as a result of leukemic transformation.

Additional small-molecule Kit inhibitors in various stages of preclinical and clinical development for the treatment of patients with mastocytosis include **MLN518,** a quinazoline-based tyrosine kinase inhibitor, which inhibits cell lines harboring Kit D816V, as well as juxtamembrane mutant-Kit; **AP23464/AP23848,** ATP-based inhibitors that have low-nanomolar inhibitory activity against Kit D816V; and **EXEL-0862,** a novel multi–tyrosine kinase inhibitor (FGFR, VEGF, PDGFR, and FLT3) that has been shown to have greater inhibitory activity against the HMC-1.2 cell line, which harbors both Kit D816V and Kit V560G, as compared with HMC-1.1, which harbors the juxtamembrane Kit V560G mutation alone.

Thus far, treatment with small-molecule kinase inhibitors has been mostly disappointing and to date has not resulted in improvement in survival. Other than rare cases of SM with specific Kit mutations involving the transmembrane domain (F522C

Continued

Investigational Therapies for Patients With Systemic Mastocytosis—cont'd

and K5091) that are exquisitely responsive to imatinib therapy, therapeutic intervention is largely palliative, aimed at alleviating skin manifestations (urticaria, pruritus) and gastrointestinal complaints (nausea, vomiting, diarrhea, abdominal pain) and avoiding severe anaphylactic reactions.

Non–Tyrosine Kinase Inhibitors

17-AAG (17-[Allylamino]-17-demethoxygeldanamycin) is a geldanamycin derivative that binds to heat shock protein 90 (Hsp90), thus enhancing the proteasomal degradation of several Hsp90 client kinases, including mutant Kit. In one report, a dose-dependent decrease in phosphorylation of Kit, AKT, and STAT3 was observed in both HMC-1.1 and HMC-1.2 cells. Furthermore, 17-AAG inhibited patient-derived neoplastic mast cells ex vivo, relative to mononuclear cells. 17-AAG is currently in phase II clinical trials for the treatment of mastocytosis. STA-9090 is another novel Hsp90 inhibitor that has shown preclinical activity in growth inhibition, caspase 3/7-dependent apoptosis, and downregulation of phosphorylated Kit in malignant mast cell lines and in primary malignant mast cells expressing wild-type or D816V Kit.

IMD-0354 is an NF-κB inhibitor that has been shown to suppress neoplastic mast cell proliferation preferentially over that of normal mast cells. Cyclin D3 expression was shown to be depressed after HMC-1 cells were exposed to IMD-0354, suggesting that constitutive activation of Kit by D816V mutation promotes NF-κB activity and the downstream upregulation of cyclin D3, leading to cell cycle progression.

Polo-like kinase-1 (PLK1) is a serine/threonine kinase that plays an essential role in mitosis and has recently been shown to be active in primary neoplastic mast cells and MCL cell lines. **BI2536** is a small-molecule inhibitor of PLK1 that has been evaluated in preclinical studies and demonstrated antiproliferative activity in SM cell lines and primary neoplastic mast cells (with associated mitotic arrest and apoptosis), but not in normal mast cells. This drug acted in synergy with midostaurin in inhibiting in vitro growth of neoplastic cells.

Obatoclax (GX015-070) inhibits BCL-2/BCL-XL and MCL 1, which has been shown to be expressed in SM. In vitro studies have shown antiproliferative effects in both SM primary cells and cell lines; these effects were augmented when obatoclax was combined with bortezomib, a proteasome inhibitor that promotes the expression of Bim.

SMA-ZnPP and **PEG-ZnPP** are Hsp32 inhibitors that target Kit-inducible heme oxygenase-1 (HO-1) in neoplastic mast cells and inhibit proliferation of SM cell lines in vitro. Hsp32 inhibitors cooperate with midostaurin in suppressing proliferation and inducing apoptosis in mast cells. Hsp32 appears to be an important survival factor in SM and serves as a novel drug target in future clinical trials.

RAD001 (everolimus) is a novel oral mammalian target of rapamycin (mTOR) inhibitor that was tested in an open-label phase II study in 10 patients with SM. Since constitutive Kit signaling leads to activation of the mTOR pathway, preclinical rationale was established for the use of this oral agent in SM. Although four patients experienced a subjective improvement in symptoms for a median duration of 3 months, no objective clinical responses were seen.

Homoharringtonine is a protein synthesis inhibitor that has been shown to inhibit the in vitro growth of imatinib-sensitive HMC-1.1 cells harboring the Kit V560G mutation and imatinib-resistant HMC-1.2 cells harboring the Kit V560G and D816V mutations. Additionally, in a murine MCL model with imatinib-resistant Kit D814Y mast cells, antitumor activity with homoharringtonine was observed, and mice had prolonged survival. The antiproliferative and proapoptotic activity was associated with inhibition of Kit-dependent phosphorylation of downstream signaling molecules such as AKT, STAT3/STAT5, and ERK1/2. Evaluation of homoharringtonine in clinical trial is warranted.

Since CD25 is almost universally and aberrantly expressed on the surface of neoplastic mast cells in patients with SM, it may serve as a novel therapeutic target. **Denileukin diftitox (Ontak)** is a DNA-derived cytotoxic protein composed of the amino acid sequences of diphtheria toxin fragments A and B and IL-2 amino acid sequences, which directs the agent to the IL-2 receptor (of which CD25 is a subunit). A pilot study conducted in eight symptomatic treatment–naive and refractory SM patients failed to show any clinical activity or any reduction in marrow mast cell burden or tryptase level with denileukin diftitox treatment. It is thought that the disappointing results of this trial are due to the finding that coexpression of the other IL-2 receptor subunits is lacking in malignant mast cells and is required for optimal binding of this agent.

Since mast cells are known to be a rich source of inflammatory cytokines (such as TNF-α and IL-6) and these cytokines may play a role in the pathogenesis of SM, a pilot study was conducted of two patients with SM-AHNMD myeloma who were treated with **lenalidomide (Revlimid),** an immunomodulating drug with potent activity in patients with myelodysplastic syndrome and 5q minus syndrome and active in the treatment of multiple myeloma. At a daily dose of 10 mg, lenalidomide did not improve SM features such as bone marrow mast cell burden, serum tryptase levels, or SM-related symptoms. In vitro studies also failed to show a signal of activity of lenalidomide in primary mast cells from the patients with aggressive or indolent SM or in HMC-1 cell lines. It is unlikely that larger clinical trials with lenalidomide in SM will be pursued.

evidence-based therapies for this disorder. Although the therapy of SM patients needs to be individualized, the general approaches to therapy are described in the following treatment sections. When appropriate, clinical trial options should be considered for SM patients requiring therapy (see box on Investigational Therapies for Patients With Systemic Mastocytosis). We refer the reader to specialized dermatology texts for the treatment of cutaneous mastocytosis.

Treatment of Mast Cell Degranulation Symptoms

Although mast cell cytoreductive agents (e.g., interferon, chemotherapy) can often effectively ameliorate symptoms of mast cell degranulation, these agents may have significant adverse effects; hence the initial approach to these patients emphasizes measures to prevent mast cell degranulation, as well as use of medications for symptom relief. In all cases, avoidance of triggers for mast cell degranulation (e.g., animal venoms, extremes of temperature, mechanical irritation, alcohol, emotional and physical stress) remains the cornerstone of therapy. Some patients cannot tolerate certain drugs or chemicals such as opioid analgesics, alcohol, aspirin or other nonsteroidal antiinflammatory medications and contrast dyes; the patient history often provides useful clues in this regard. A detailed workup to provide allergen avoidance guidelines is recommended in patients with mastocytosis. Skin testing can be done safely, and the results correlate with the symptoms of allergy- and antigen-specific IgEs. Lifelong venom immunotherapy should be considered in patients with IgE-mediated Hymenoptera venom allergy. Furthermore, appropriate precautionary measures during anesthesia and surgery are recommended in these patients.

Noncytoreductive therapy of mast cell degranulation symptoms includes the use of oral H_1- (e.g., hydroxyzine, diphenhydramine, fexofenadine, cetirizine, cyproheptadine, chlorpheniramine) and H_2- (e.g., ranitidine, famotidine) antihistamines for pruritus and peptic ulcer symptoms, respectively, and orally administered cromolyn sodium for nausea, abdominal pain, and diarrhea. Use of the latter is supported by Level I evidence. In a double-blind crossover study, cromolyn sodium was found to be therapeutically equivalent to a combination of cimetidine and chlorpheniramine for the treatment of mastocytosis-related symptoms. Corticosteroids are occasionally

used for treating recurrent hypotensive episodes, ascites, and diarrhea with malabsorption. Patients with a propensity toward vasodilatory shock should wear a medical alert bracelet and carry an EpiPen injector for self-administration of subcutaneous epinephrine. In the rare case of a patient with severe and/or recurrent life-threatening degranulation-related events that are refractory to the aforementioned agents, cautious consideration may be given to the use of cytostatic or cytoreductive agents (such as 2-CdA); however, the potential adverse effects, including potentially mutagenic effects, of such agents must always be kept in mind and their use should be preceded by a full discussion of the potential risks and benefits with the patient.

Treatment of Organomegaly/Organopathy Symptoms

Cytoreductive therapy, especially chemotherapy, is generally reserved for patients with progressive symptomatic disease and for organopathy (C findings) that is directly related to tissue mast cell infiltration. In certain patients, however, it can be difficult to distinguish whether the organopathy relates to mast cell infiltration or whether it represents an immunologic response to the disease or an associated non–mast cell neoplasm (SM-AHNMD). Currently used first- and second-line therapeutic agents include the following:

Interferon-Alpha (IFN-α)

Interferon-alpha (IFN-α) is often considered the first-line therapy for progressive symptomatic disease, including in the presence of a concurrent non–mast cell myeloproliferative disorder (e.g., CMML). IFN-α is generally started at the dose of 1 million units (MU) subcutaneously three times per week, followed by gradual escalation to 3 to 5 MU three to five times per week, if tolerated. IFN-α (with or without concomitant corticosteroids for synergistic effect) has been reported to improve symptoms of mast cell degranulation, decrease bone marrow mast cell infiltration, and ameliorate mastocytosis-related ascites/hepatosplenomegaly, cytopenias, skin findings, and osteoporosis. Overall response rates to IFN-α therapy are approximately 20% to 60% (depending on the subtype), but they are extremely difficult to estimate, given the heterogeneous presentation of patients with mastocytosis, use of variable treatment dosages, generally short follow-up, and use of nonuniform treatment response criteria in published studies. The optimal dose and duration of IFN-α therapy for systemic mastocytosis remains uncertain. In a prospective multicenter study, all four patients receiving the highest IFN-α dose (i.e., >3 MU/m^2/day) responded to treatment. The time to best response may be up to 12 months or longer and delayed responses to therapy have been described. The addition of prednisone at doses of 20 to 60 mg/day with a slow taper over weeks to months did not appear to improve the response rates, but it can improve tolerability of IFN-α. A significant proportion of patients may experience clinical and/or biochemical relapse within several months of IFN-α treatment being discontinued, highlighting the largely cytostatic effect of IFN-α on neoplastic mast cells. IFN-α is associated with a variable, but significant, incidence (up to 50%) of dose-limiting toxicity, including flu-like symptoms, bone pain, fever, worsening cytopenias (particularly in patients with baseline organomegaly/cytopenias), depression, retinitis, and hypothyroidism. Anaphylaxis, as a response to IFN-α injections, has been described. Consequently, the dropout rate with IFN-α treatment due to adverse events is not trivial, and whether the addition of corticosteroids to IFN-α improves either treatment tolerance or efficacy remains to be proven in a randomized setting.

2-Chlorodeoxyadenosine/Cladribine

Single-agent 2-chlorodeoxyadenosine/cladribine (2-CdA) is effective in treating all subgroups of IFN-α refractory/intolerant SM patients; variable treatment schedules have been used in this setting. In SSM, 2-CdA can effectively reduce mast cell burden and improve symptoms, but in rapidly progressive ASM and MCL, this agent alone may not be effective in inducing durable responses. In a prospective multicenter pilot study of 10 patients, 2-CdA (0.1 to 0.13 mg/kg by a 2-hour IV infusion on days 1 through 5 every 4 to 8 weeks for 6 cycles) was found to be therapeutically active in all mastocytosis subsets. Although all patients had a clinical response, and bone marrow mast cell cytoreduction was also noted in 9 of 10 patients, no complete remissions were observed. Also, in a preliminary report of 33 SM patients treated with 2-CdA (0.15 mg/kg by a 2-hour IV infusion or subcutaneously for 5 days every 4 to 12 weeks for 1 to 6 cycles), major, partial, or no responses were seen in 24, 2, and 7 patients, respectively. Twenty six patients (first- and second-line therapy) were treated with 2-CdA at doses of 5 mg/m^2 or 0.13 to 0.17 mg/kg/day for 5 days as a 2-hour intravenous infusion. At a median of 3 cycles (range 1-9), an objective response rate (ORR) of 55% was observed and was essentially uniform in response throughout subcategories. Myelosuppression was the major adverse effect seen in approximately one-third of cases in each study. In a French study, 44 SM patients that had either failed symptomatic therapy and/or IFN therapy were treated with 2-CdA at 0.15 mg/kg/day for 5 days every 1 to 2 months for a median of 4 cycles. The median time to response was 20 months, and ORRs were 89%, 58%, 67%, 100% in ISM, ASM, CM, SSM, respectively.[26] Responses were seen in individual symptoms, normalization of eosinophil counts, and improved tryptase levels.

Imatinib Mesylate (Gleevec)

Imatinib mesylate (Gleevec) is an orally bioavailable small-molecule inhibitor of Kit, ABL, Arg, and PDGFR tyrosine kinases. The identification of gain-of-function mutations involving Kit and PDGFRA genes (known imatinib targets) in the pathogenesis of systemic mastocytosis has obvious therapeutic implications in this regard. Consistent with predictions from in vitro data, the clinical experience to date suggests that the vast majority of mastocytosis patients (who harbor Kit D816V) are likely to be refractory to imatinib therapy. In contrast, clinically meaningful responses have been observed for patients with wild-type Kit–associated mastocytosis and rare patients with Kit juxtamembrane mutations (e.g., F522C, K509I), suggesting that this subgroup of patients has imatinib-responsive disease. Imatinib has largely had disappointing results in clinical trials of patients with mastocytosis, and this is in large part due to the high frequency of D816V expression in patients, which is predictive for nonresponse. Overall response rates have ranged from 18% to 36% and include improvements in symptoms, UP, and organomegaly, as well as reduction in MC bone marrow burden and other biomarkers (e.g., serum tryptase). A response rate of 36% in Kit D816V–positive patients has been reported in one study,[27] whereas in another study, no patients with Kit D816V responded. In a Mayo Clinic study, the highest response rate was seen in SM-AHNMD. The drug has been used at a starting dose of 400 mg daily (+/– initial low-dose steroids) with a taper to 200 mg daily in responding patients that continue to receive maintenance therapy.

Patients with bone marrow involvement by abnormal mast cells who harbor FIP1L1-PDGFRA also uniformly achieve complete clinical, histologic, and molecular/cytogenetic responses with low-dose imatinib therapy, in the absence of mutations that confer imatinib resistance (PDGFRAT764I), which may be acquired with clonal evolution. Finally, imatinib is predicted to be effective in SM with specific mutations such as V560G and del419, although clinical proof of this supposition is lacking to date. The remarkable efficacy of imatinib in treating mastocytosis patients harboring specific mutations provides proof of principle for the development of molecularly targeted therapies for this disease, as well as a treatment-relevant molecular classification. It is currently recommended that patients with primary eosinophilia, particularly in the presence of increased bone marrow mast cells or increased serum tryptase level (i.e., SM-CEL), be screened for the presence of FIP1L1-PDGFRA by either FISH or reverse transcriptase–polymerase chain reaction (RT-PCR). Imatinib mesylate, generally at the 100-mg daily dose level, is considered to be first-line therapy for this group of patients. Initiation

of imatinib therapy in patients with clonal eosinophilia harboring FIP1L1-PDGFRA can rarely lead to cardiogenic shock, resulting from rapid onset of eosinophil lysis/degranulation in the endomyocardium. Consequently, consideration may be given to starting imatinib concurrently with corticosteroids, particularly in the presence of either an abnormal echocardiogram or an elevated serum troponin level before treatment. In contrast to its effectiveness with FIP1L1-PDGFRA, most studies show that imatinib is not therapeutically beneficial for patients carrying Kit D816V, who make up the majority of SM patients. This mutation maps to the Kit enzymatic site and disrupts the imatinib-binding site. For patients harboring D816V or those without detectable imatinib-sensitive mutations, IFN-α may represent an attractive initial treatment option. Although a modest clinical benefit may be observed with imatinib at 400 mg daily in some patients without either Kit D816V or FIP1L1-PDGFRA, the use of imatinib in this setting remains investigational. Currently, imatinib is the only FDA-approved drug for the treatment of SM and is specifically indicated in the treatment of adult patients with ASM who do not have Kit D816V or who have an unknown mutation status.

In patients in whom symptomatic therapy is not sufficient and cytoreductive therapy is not effective, hematopoietic stem cell transplantation (HSCT) can be considered. Only limited reports exist of HSCT with myeloablative conditioning. A pilot study of three SM patients treated with a nonmyeloablative HSCT using an HLA-identical sibling has been reported. A highly immunosuppressive conditioning regimen was used to reduce transplant-related mortality (TRM) while allowing for engraftment and the induction of a graft-versus-mast-cell (GVMC) effect. Although TRM was not an issue, mast cell degranulation events complicated the treatment in two of the three cases. The three patients experienced progressive disease, and the longest duration of response was 39 months. Optimal cytoreduction with cladribine or interferon prior to HSCT may improve the ability of nonmyeloablative HSCT to effectively exploit the GVMC effect and lead to durable remissions and possibly cure in cases of aggressive SM. Currently, HSCT remains experimental in the treatment of SM.

FUTURE DIRECTIONS

The approach to a patient with systemic mastocytosis continues to be challenging, with many unanswered questions relating to aspects of (a) diagnosis, (b) pathogenesis, (c) clinical presentation, and (d) treatment of this heterogeneous disorder. At the diagnostic interface, a uniform approach to molecular testing is lacking at present; consensus is needed regarding the specific molecular assay(s) as well as biologic material(s) that are considered optimal for mutation analysis in mastocytosis patients. Advances in the understanding of SM pathogenesis have identified a number of potential drug targets in addition to Kit. Although effective control of MC mediator-related symptoms is obtained in most cases, effective control of mast cell burden is not uniformly controlled with current therapeutic strategies, and an unmet need for improved treatment approaches continues to exist. Ongoing and future clinical trials need to combine tyrosine kinase inhibitors, chemotherapeutics, and other novel agents that target Kit-independent oncogenic pathways in synergistic antiproliferative activity directed against the neoplastic mast cell. Optimally, what is needed are innovative, well-designed clinical trials combining agents directed against relevant molecular and biologic targets in the neoplastic mast cells that are conducted in cooperative multiinstitutional settings.

CHAPTER 72

PATHOLOGIC BASIS FOR THE CLASSIFICATION OF NON-HODGKIN AND HODGKIN LYMPHOMAS

Elaine S. Jaffe, Stefania Pittaluga, and John Anastasi

The classification of malignant lymphomas has undergone significant changes over the past 50 years. The current approach is based on the integration of morphologic, phenotypic, genetic, and clinical features that allows the identification of distinct disease entities (see box on Principles of the Classification of Lymphomas Based on the REAL/WHO Classifications). This practical approach to lymphoma categorization was initially proposed by the International Lymphoma Study Group in 1994 and formed the basis of the Revised European-American Classification of Lymphoid Neoplasm (REAL). It was then adopted by the World Health Organization (WHO) classification of neoplasms of the hematopoietic and lymphoid tissues, published in 2001 and updated in 2008 (Table 72-1). The WHO classification represents a significant achievement in terms of cooperation, communication, and consensus among pathologists, hematologists, and oncologists. Furthermore, it recognizes that any classification system, in order to be viable and applicable, should evolve and incorporate new data resulting from emerging technologies in the field of hematopathology as shown by the inclusion of gene expression profiling (GEP) data in the more recent edition. These studies have led to the identifications of new prognostic and diagnostic categories. Major improvements in sequencing technologies now provide a great opportunity to examine the cancer genome for large-scale identification of genomic alterations in a more comprehensive manner, and by combining analysis of genome, transcriptome, and exome sequences, new insights will be gained into pathogenetic mechanisms and implementation of more targeted and personalized therapies.

Principles of the Classification of Lymphomas Based on the Revised European-American Classification of Lymphoid Neoplasm/World Health Organization Classifications

- Each disease is defined as a distinct entity based on a constellation of morphologic, clinical, and biologic features.
- The cell of origin is the starting point of disease definition.
- Some lymphoid neoplasms can be identified by routine morphologic approaches. However, for most diseases, knowledge of the immunophenotype and molecular genetics or cytogenetics plays an important role in differential diagnosis.
- A disease-based approach to classification facilitates discovery of molecular pathogenesis.
- The sites of presentation and involvement are important clues to underlying biologic distinctions. Extranodal lymphomas differ in many respects from their nodal counterparts.
- Many lymphoma entities display a range in cytologic grade and clinical aggressiveness, making it difficult to stratify lymphomas according to clinical behavior. A number of prognostic factors influence clinical outcome, including stage, international prognostic index, cytologic grade, gene expression profile, secondary genetic events, and the host environment.

This chapter focuses on the classification of neoplasms derived from mature B cells, T cells, and natural killer (NK) cells with emphasis on malignant lymphoma. The chapter provides a framework for the subsequent chapters on Hodgkin lymphoma and non-Hodgkin lymphoma (NHL) in reviewing the major entities according to the WHO classification.

PRECURSOR B-CELL AND T-CELL NEOPLASMS

B-Lymphoblastic Leukemia and Lymphoma

Most B-lymphoblastic leukemias and lymphomas (B-LBL) present as leukemia; lymphomatous presentations occur in approximately 5% to 10% of cases. Frequent sites of involvement include the lymph nodes, skin, soft tissue, and bone. Skin lesions in children frequently present in the head and neck region, including the scalp. Progression to leukemia occurs in the vast majority of cases if a complete remission is not obtained. The disease is most common in children and young adults.

Cytologically, B-LBL is composed of lymphoblasts that are usually somewhat larger than small lymphocytes but smaller than the cells of diffuse large cell lymphoma (Fig. 72-1). The cells have finely stippled chromatin with sparse cytoplasm and inconspicuous nucleoli. The nuclei may be round or convoluted. Mitotic figures are common, in keeping with the high-grade nature of the neoplasm. The differential diagnosis of B-LBL includes blastic plasmacytoid dendritic cell neoplasm, which can occur in children, and shows a marked predilection for skin. Extensive immunophenotypic studies are required for the differential diagnosis.

The lymphoblasts of B-LBL usually express markers of B-cell lineage such as CD19, PAX-5, and cytoplasmic CD22. They often lack CD20, which is usually expressed at later stages of B-cell differentiation after light chain gene rearrangement has occurred. PAX-5, a B-cell transcription factor, is a useful diagnostic marker in this instance. However, it should be noted that PAX-5 is not restricted to the B-cell lineage and may be expressed in some neuroendocrine carcinomas, particularly Merkel cell carcinoma, which is often in the differential diagnosis of small blue round cell tumors involving the skin.

In the 2008 WHO classification, B-LBL is further subdivided into distinct subsets characterized by recurrent genetic abnormalities. These are associated with distinctive clinical or phenotypic features and have important prognostic implications.

The impact of new technologies in the classification of lymphoblastic leukemia and lymphoma and targeted therapy are addressed in Chapters 63 and 64.

T-Lymphoblastic Lymphoma and Leukemia

Most lymphoblastic lymphomas and leukemias (T-LBLs) are cytologically indistinguishable from their B-cell counterparts. The blasts have finely distributed chromatin, inconspicuous nucleoli, and sparse pale cytoplasm. Nuclear irregularity is variable. This is a disease of adolescents and young adults, with an increased male-to-female ratio.

Table 72-1 World Health Organization Classification of Tumors of Hematopoietic and Lymphoid Tissues (2008)*

B-cell lymphoblastic leukemia/lymphoma
Multiple variants listed based on cytogenetic findings
B-cell lymphoblastic leukemia/lymphoma

MATURE B-CELL NEOPLASMS

Chronic lymphocytic leukemia/small lymphocytic lymphoma
B-cell prolymphocytic leukemia
Splenic marginal zone lymphoma
Hairy cell leukemia
Splenic B-cell lymphoma/leukemia, unclassifiable
Splenic diffuse red pulp small B-cell lymphoma
Hairy cell leukemia—variant
Lymphoplasmacytic lymphoma
Waldenström macroglobulinemia
Heavy chain diseases
α-Heavy chain disease
γ-Heavy chain disease
μ-Heavy chain disease
Plasma cell myeloma
Solitary plasmacytoma of bone
Extraosseous plasmacytoma
Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)
Nodal marginal zone lymphoma
Pediatric nodal marginal zone lymphoma
Follicular lymphoma
Pediatric follicular lymphoma
Primary cutaneous follicle center lymphoma
Mantle cell lymphoma
Diffuse large B-cell lymphoma (DLBCL), not otherwise specified
T-cell/histiocyte rich large B-cell lymphoma
Primary DLBCL of the central nervous system
Primary cutaneous DLBCL, leg type
EBV positive DLBCL of the elderly
DLBCL associated with chronic inflammation
Lymphomatoid granulomatosis
Primary mediastinal (thymic) large B-cell lymphoma
Intravascular large B-cell lymphoma
ALK-positive large B-cell lymphoma
Plasmablastic lymphoma
Large B-cell lymphoma arising in human herpesvirus 8–associated multicentric Castleman disease
Primary effusion lymphoma
Burkitt lymphoma
B-cell lymphoma unclassifiable, with features intermediate between diffuse large B-cell lymphoma and Burkitt lymphoma
B-cell lymphoma unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classical Hodgkin lymphoma

MATURE T-CELL AND NATURAL KILLER (NK) CELL NEOPLASMS

T-cell prolymphocytic leukemia
T-cell large granular lymphocytic leukemia
Chronic lymphoproliferative disorder of NK cells
Aggressive NK cell leukemia
Systemic EBV positive T-cell lymphoproliferative disease of childhood
Hydroa vacciniforme-like lymphoma
Adult T-cell leukemia/lymphoma
Extranodal NK cell/T-cell lymphoma, nasal type
Enteropathy-associated T-cell lymphoma
Hepatosplenic T-cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Mycosis fungoides
Sézary syndrome
Primary cutaneous CD30-positive T-cell lymphoproliferative disorders
Lymphoid papulosis
Primary cutaneous anaplastic large cell lymphoma
Primary cutaneous γ-δ T-cell lymphoma
Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma
Primary cutaneous CD4-positive small/medium T-cell lymphoma
Peripheral T-cell lymphoma, not otherwise specified
Angioimmunoblastic T-cell lymphoma
Anaplastic large cell lymphoma, ALK positive
Anaplastic large cell lymphoma, ALK negative

HODGKIN LYMPHOMA

Nodular lymphocyte predominant Hodgkin lymphoma
Classical Hodgkin lymphoma
Nodular sclerosis Hodgkin lymphoma
Lymphocyte-rich classical Hodgkin lymphoma
Mixed cellularity classical Hodgkin lymphoma
Lymphocyte-depleted classical Hodgkin lymphoma

*Provisional entities are shown in *italics*.

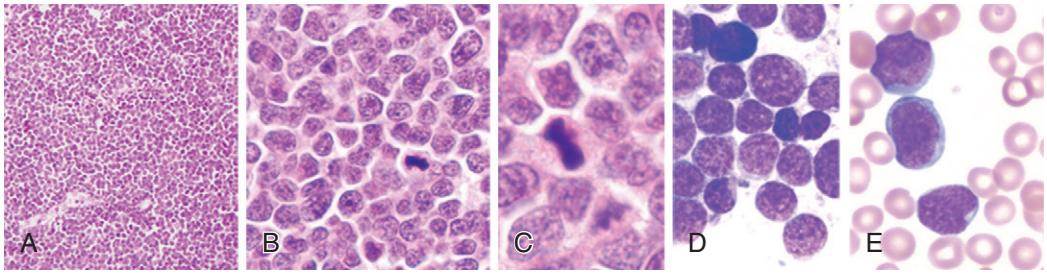

Figure 72-1 LYMPHOBLASTIC LYMPHOMA. Low-power **(A)** and higher power **(B)** views showing a diffuse infiltrate of intermediate-sized cells with high mitotic rate and finely dispersed "blastic" nuclear chromatin **(C).** Touch imprints performed at the time of the biopsy **(D)** illustrate the fact that the lymphoma cells are nearly identical to circulating lymphoblasts seen in acute lymphoblastic leukemia **(E).** The precursor B type cannot be easily distinguished from the precursor T-cell type without immunophenotyping.

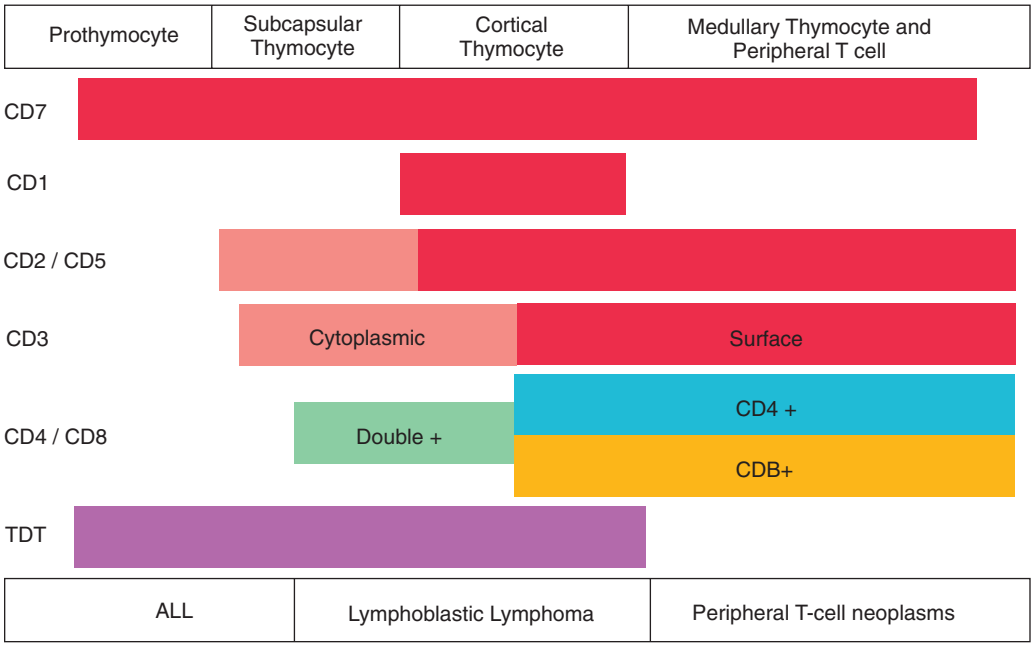

Figure 72-2 T-CELL NEOPLASMS RELATED TO STAGES OF T-CELL DIFFERENTIATION. *ALL,* Acute lymphoblastic leukemia.

About 50% to 80% of patients present with an anterior mediastinal mass, usually with involvement of the thymus gland. This is a high-grade lymphoma; the rapidly growing mass may be associated with airway obstruction. Bone marrow (BM) involvement is common, and progression to a leukemic picture occurs in the absence of effective therapy.

In lymph nodes, T-LBL has a diffuse pattern of infiltration. There is little stromal reaction, and the blasts infiltrate the nodal parenchyma with streaming of cells around vascular structures and spilling over the capsule. Mitotic figures are frequent with a starry-sky pattern seen in approximately one-third of cases.

By immunophenotypic studies, the blasts have an immature T-cell phenotype that correlates with different stages of intrathymic maturation based on the expression of numerous transcription factors. The blasts also express terminal deoxynucleotidyl transferase (TdT) (Fig. 72-2). The earliest T cell–associated antigen with some lineage specificity is CD7. However, it is also expressed in rare cases of acute myeloid leukemia as evidence of lineage infidelity, often present in primitive hematopoietic malignancies. CD3, linked to the T-cell antigen receptor, is detectable in the cytoplasm before its surface expression and thus may be negative when examined on fresh cells or by routine flow cytometry unless permeabilization techniques are used to detect cytoplasmic antigens. It should be noted that the normal thymocytes encountered in a lymphocyte-rich thymoma are phenotypically similar to the cells detected in T-LBL. The differential diagnosis can be quite challenging, especially on needle core biopsies and immunohistochemical analysis, and molecular studies may be necessary. The classification of B-LBL and T-LBL has attained greater accuracy and prognostic significance through the application of GEP, copy number analysis, and genome-wide profiling of structural DNA alterations.[1]

MATURE B-CELL NEOPLASMS

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) usually presents in adults with generalized lymphadenopathy, frequent BM and peripheral blood involvement, and often hepatosplenomegaly. Presentation as leukemia, that is, CLL, is more common than as lymphoma, SLL. Even in patients with a lymphomatous presentation, careful examination of the blood may reveal a circulating monoclonal B-cell component. Nevertheless, some patients present with generalized adenopathy, and although progression to CLL is frequent, it does not necessarily occur in all cases.

The increased sensitivity of immunophenotypic and molecular methodologies has resulted in the detection of clonal lymphoid proliferations with a CLL phenotype in the general population even in the absence of clinical lymphocytosis, a condition now designated monoclonal B-cell lymphocytosis (MBL) (see box on Early Events in Lymphoid Neoplasia). The International Workshop on CLL proposed new diagnostic criteria that were then included in the WHO classification of 2008. Recent studies have indeed shown that the absolute count of monoclonal B cells greater than 5.0×10^9/L is clinically more relevant than the absolute lymphocyte count in predicting outcome.[2] Similar to peripheral blood, small clonal populations with a CLL phenotype can be detected in lymph nodes as an incidental finding and appear to represent a tissue counterpart of MBL.[3] At a recent workshop of the European Association for Haematopathology and the Society of Hematopathology (Uppsala, September 2010), the term *lymph node involvement by monoclonal CLL-type B cells of unknown clinical significance* was suggested for such lesions, borrowing from terminology of plasma cell neoplasms.

Histologically, the lymph node involved by CLL/SLL shows diffuse architectural effacement (Fig. 72-3), although occasional residual naked germinal centers can be observed. The predominant cell type is a small lymphocyte with clumped chromatin, but a spectrum of nuclear morphology is usually seen. Pseudofollicular growth centers or proliferation centers are present in the majority of cases and contain a spectrum of cells ranging from small lymphocytes to prolymphocytes and paraimmunoblasts. The prolymphocytes and paraimmunoblasts have more dispersed chromatin and more prominent nucleoli usually centrally placed. The presence of proliferation centers is also a helpful criterion in the differential diagnosis with mantle cell lymphoma (MCL), which may show otherwise some overlapping features with CLL. If needed, immunophenotypic studies can be helpful in this differential diagnosis.

CLL/SLL is characterized by $CD5^+$, $CD23^+$, B cells expressing dim CD20, and usually dim surface immunoglobulin (sIg). The lack of staining for Cyclin D1 can help rule out MCL. CLL has been shown

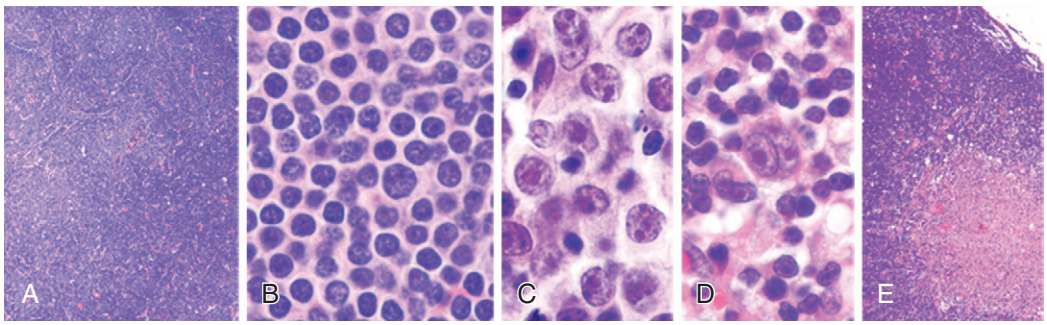

Figure 72-3 SMALL LYMPHOCYTIC LYMPHOMA (SLL). Low-power view **(A)** illustrates a diffuse effacement of the lymph node. A monotonous population of small lymphocytes is seen at higher power **(B).** These have fairly round nuclear contours, condensed nuclear chromatin, and inconspicuous or absent nucleoli. Only rare larger cells are present. SLL can transform to large cell lymphoma **(C)** and occasionally to Hodgkin lymphoma **(D).** Patients can also develop worsening lymphadenopathy from viral infections such as herpes simplex virus, in which the node typically shows focal necrosis **(E).**

Early Events in Lymphoid Neoplasia

- In recent years, there has been a greater appreciation of early events in lymphoid neoplasia.
- These early lesions can in some ways be considered equivalent to benign neoplasms in the epithelial system.
- These are clonal proliferations of B cells or T cells that carry genetic aberrations associated with specific forms of lymphoid neoplasia, including CLL, multiple myeloma, follicular lymphoma, and mantle cell lymphoma.
- Examples include monoclonal gammopathy of undetermined significance, MBL, follicular lymphoma in situ, mantle cell lymphoma in situ, lymphomatoid papulosis, patch stage of mycosis fungoides, and primary cutaneous $CD4^+$ small/medium T-cell lymphoma.
- Early lesions appear to lack the secondary and tertiary "hits" seen in lymphoid neoplasms that are clinically significant, and most patients have a very low risk of clinical progression.
- Challenges for the future are:
 - To define the precise genetic features that distinguish early lesions from lymphoma.
 - To assess the risk of clinical progression.
 - To determine how these patients should be managed clinically.

to have a greater degree of heterogeneity biologically, and different subgroups have been identified based on immunoglobulin heavy chain mutational status, cytogenetics, ZAP-70 expression, and CD38 expression.[4] The latter two have been used as partial surrogate markers for the mutational status. ZAP-70 expression correlates with an unmutated status and a poorer prognosis. In fact, ZAP-70 expression has been suggested to be more clinically relevant than mutation status when the two markers are discordant. The use of CD38 as a surrogate marker for mutational status is less useful, but its high expression is also associated with a poor prognosis. Recently, additional new recurrent somatic mutations have been identified in CLL using whole-genome and -exome sequencing techniques, and some of them have been associated with clinical outcome.[5]

Histologic transformation over time may occur in CLL, a phenomenon known as Richter syndrome. Short of progression to diffuse large B-cell lymphoma (DLBCL), lymph nodes may show an increased number of prolymphocytes and paraimmunoblasts, recently proposed as "accelerated phase."[6] A Hodgkin-like transformation has also been described in CLL/SLL. This transformation can take one of two forms. In some cases, Reed-Sternberg (RS) cells and mononuclear variants are seen in a background of small round B lymphocytes, consistent with CLL. The process lacks the rich inflammatory background characteristic of Hodgkin lymphoma, such as eosinophils, plasma cells, and histiocytes. However, patients with this type of Hodgkin transformation appear to progress to a process that is more typical of Hodgkin lymphoma, with loss of the B-cell small lymphocytic component. In other instances, classical Hodgkin lymphoma (CHL) of the mixed cellularity or nodular sclerosis subtype may be seen in patients with a history of CLL. Studies have implicated Epstein-Barr virus (EBV) in the Hodgkin type of Richter transformation. The RS cells and variants are EBV positive and in some cases have been shown to be derived from the CLL clone. In other instances, diverse clonal origins are shown.

Lymphoplasmacytic Lymphoma

The term lymphoplasmacytic lymphoma (LPL) should be limited to cases that do not fulfill the criteria for any other type of B-cell neoplasm with plasmacytic differentiation. Also, the definition of Waldenström macroglobulinemia (WM) and its relationship to LPL have been complex. The WHO classification (2008) adopted the approach advocated at the second international workshop on WM, which defined WM as the presence of an IgM monoclonal gammopathy of any concentration associated with BM involvement by LPL.[7] Hence, LPL and WM are not synonymous, with WM defying a subset of LPL.

This is a disease of adult life that usually presents with BM involvement and sometimes with nodal and splenic involvement (splenomegaly), vague constitutional symptoms, and anemia (see Chapter 86). The tumor consists of a diffuse proliferation of small lymphocytes, plasmacytoid lymphocytes, and plasma cells, with or without Dutcher bodies (see Fig. 72-4). The growth pattern is often interfollicular with sparing of the sinuses. The cells have surface and cytoplasmic Ig, usually of IgM type, usually lack IgD, and express B cell–associated antigens (CD19, 20, 22, 79a). They are usually negative for CD5 and CD10. CD25 or CD11c may be weakly expressed in some cases. The lack of CD5 and the presence of strong cytoplasmic Ig are useful in distinction from CLL. The postulated normal counterpart is thought to be a postfollicular medullary cord B cell based in part on the presence of somatic mutations in the Ig heavy- and light-chain variable region genes.

Deletion of 6q21–22.1 occurs in about half of cases but is not a specific finding.[8a] LPL shows morphological and immunophenotypic overlap with some cases of marginal zone lymphoma with plasmacytic differentiation. Recent studies have identified recurrent mutations of *MYD88* in LPL but not in marginal zone lymphomas, confirming these are distinct entities, and providing a genetic test for diagnosis.[8b]

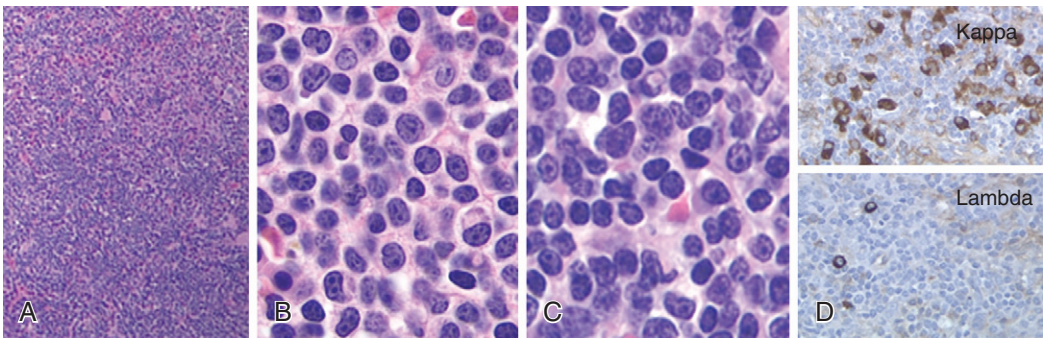

Figure 72-4 LYMPHOPLASMACYTIC LYMPHOMA (LPL). LPL and Waldenström macroglobulinemia have nearly identical morphology. There is a diffuse infiltrate **(A)** of small lymphocytes that have plasmacytoid features or interspersed plasma cells (**B,** bone marrow; **C,** lymph node). Intranuclear inclusions can sometimes be seen. Evaluation for κ and λ by immunohistochemical stains can demonstrate clonality in the plasma cells and plasmacytoid lymphocytes **(D).**

Mantle Cell Lymphoma

Mantle cell lymphoma is a distinct entity that has been more precisely defined in recent years through the integration of immunophenotypic, molecular genetic, and clinicopathologic studies. The molecular hallmark of MCL is the t(11;14)(q13;q32) involving cyclin D1 *(CCND1)* and the IGH@ gene. Cyclin D1 overexpression is believed to be essential in the pathogenesis of MCL. However, rare variants negative for cyclin D1 with similar immunomorphology and gene expression signature have been identified. Cyclin D1–negative forms usually express either cyclin D2 or cyclin D3, which may functionally substitute for cyclin D1. Sox11 is overexpressed in most cyclin D1–positive and –negative cases.[9]

The postulated normal counterpart is the $CD5^+$ "naive" B cell, $sIgM^+$ and $sIgD^+$, which can be found in the peripheral blood and in the mantle of reactive germinal centers. Mutational analysis of the rearranged immunoglobulin variable region genes shows few or no somatic mutations; however, similarly to CLL, a subset of MCL has mutated *IG* genes.

Recently, because of the widespread use of immunohistochemistry, early involvement of lymph node by cells carrying t(11;14) translocation with subsequent overexpression of cyclin D1 has been documented in several cases, so-called "in situ MCL." Most often these represent an incidental finding, but some cases eventually progress to overt MCL.[10] In some cases, in situ MCL is detected in a lymph node involved by another lymphoma type, such as follicular lymphoma (FL). The risk of progression of in situ MCL is difficult to ascertain because the number of reported cases is few. In a recent multicenter retrospective study, it was noted that the expression of SOX-11 was more frequently associated with progression to MCL because the majority of in situ cases lacked SOX-11 expression.[10] Also similar to FL in situ, a distinction should be made between partial involvement by MCL with a mantle zone pattern and in situ MCL. The latter refers to a reactive lymph node with cyclin D1–positive cells limited to an otherwise normally appearing follicle mantle; these cases tend not to progress, and they should not be labeled as lymphomas.

Another newly identified variant is an indolent form of MCL characterized by a leukemic phase without nodal disease but often with long-standing splenomegaly. These patients have an indolent clinical course and do not appear to require aggressive chemotherapy.[11] These cases carry t(11;14) with few additional chromosomal abnormalities and lack expression of SOX11 in contrast to conventional MCL.

Mantle cell lymphoma occurs in adults (median age, 62 years), with a high male-to-female ratio. Most patients present with advanced stage at diagnosis. Common sites of involvement include the lymph nodes, spleen, BM, and lymphoid tissue of Waldeyer ring. Gastrointestinal tract involvement is frequent and is associated with the picture of lymphomatous polyposis.

The hallmark of MCL is a very monotonous cellular composition. In the typical case, the cells are slightly larger than a normal lymphocyte with finely clumped chromatin, scant cytoplasm, and inconspicuous nucleoli (Fig. 72-5). The nuclear contour is usually irregular or cleaved. Some cytologic variants, blastoid (blastic) and pleomorphic, tend to be associated with a more aggressive course and adverse biologic features, such as tetraploidy or p53 mutation or deletion. The proliferation rate was previously identified as prognostically important based on scoring of Ki67-positive cells. More recently, GEP, using genes involved in cell cycle progression and DNA synthesis, has identified a proliferation signature that delineates cohorts with varied prognosis. These correlate to some extent with cytologic subtype.[12] For example, the blastoid variant has a high proliferation rate using both Ki67 and GEP.

Follicular Lymphoma

Follicular lymphoma is the most common subtype of NHL within the United States and accounts for approximately 45% of all newly diagnosed cases. It has a peak incidence in the fifth and sixth decades of life and is rare before the age of 20 years. Men and women are equally affected. FL is less common in black and Asian populations. Most patients have stage 3 or 4 disease at diagnosis, with generalized lymphadenopathy. Staging evaluation usually detects BM involvement. Approximately 10% of patients have circulating malignant cells. However, careful immunophenotypic or molecular analyses may disclose peripheral blood involvement in a higher proportion of patients. A more accurate prognostic index than the IPI, the FLIPI, has been proposed for FL and has been widely adopted.

The natural history of the disease is associated with histologic progression in both pattern and cell type (Fig. 72-6). A heterogeneous cytologic composition is one of the hallmarks of FL. Usually, all of the follicle center cells are represented but in varying proportions. It should be stressed that the variation in cytologic grade is a continuum, and therefore precise morphologic criteria for subclassification are difficult to establish.

According to the WHO classification, all low-grade FLs are combined into a single category, grade 1 to 2, all containing overall a predominance of centrocytes with fewer than 15 centroblasts per high-power field (hpf). FL grade 3 (with >15 centroblasts/hpf) is further subdivided into grades 3A and 3B based on the presence or absence of centrocytes in the background. Other factors that may influence outcome in FL include the tumor microenvironment, highlighted initially by GEP.[13]

The vast majority of FL (≈85%) are associated with a t(14;18) involving rearrangement of the *BCL2* gene. This translocation appears to result in constitutive expression of Bcl-2 protein, which is capable of inhibiting apoptosis in lymphoid cells. The cells of FL accumulate and are at risk to acquire secondary mutations, which may be

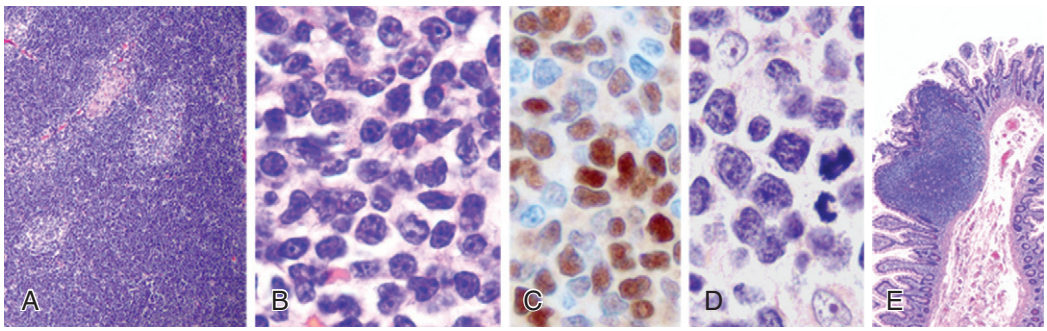

Figure 72-5 MANTLE CELL LYMPHOMA (MCL). At low power, MCL can show a diffuse, vaguely nodular, or mantle zone pattern. In the latter, the neoplastic mantle zones are expanded and can become confluent leaving "naked" germinal centers **(A).** At higher power, the lymphoma cells are small or slightly enlarged **(B).** They have irregular nuclear contours, especially compared with small lymphocytic lymphoma, and they have a dense chromatin. Typically, cases are positive for cyclin D1 expression **(C),** which is related to the t(11;14) involving IgH and *CCND1*. Some cases can develop a "blastoid" transformation **(D),** although some cases can present as a "blastoid" variant. Such cases are characterized by cells with an intermediate size, a high mitotic rate, and finely dispersed "blastic" chromatin. Sometimes when the "blastoid" cases develop a leukemic phase, they can be difficult to distinguish morphologically from acute lymphoblastic leukemia. In such cases, flow immunophenotyping is needed to resolve the differential diagnosis. MCL can also present with gastrointestinal involvement **(E)** as in lymphomatoid papulosis.

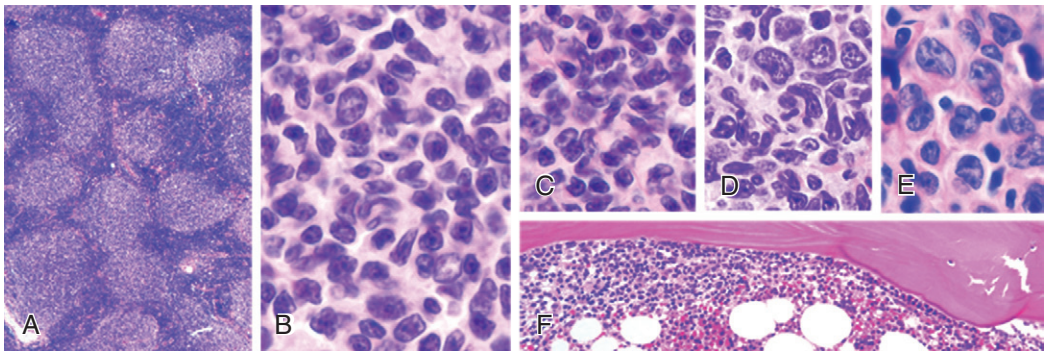

Figure 72-6 FOLLICULAR LYMPHOMA (FL). FL shows effacement of the normal lymph node architecture because of an accumulation of neoplastic lymphoid follicles that lack the features of reactive follicles **(A).** They are crowded, show back-to-back localization, lack distinct mantle zones, and show no polarity. The lymphoma cells are highly irregular **(B)** with elongated, twisted, or clefted nuclear contours and dense chromatin. FL is typically graded into grade 1 or 2 (1/2; **C, D**), or 3 **(E),** depending on the number of large cells seen at higher power (see text). FL typically involves the bone marrow with lymphoma cells spreading along the bone **(F).** This localization is termed "paratrabecular."

associated with histologic progression. It has been postulated that the *BCL2/IGH@* translocation occurs during immunoglobulin gene rearrangement in the BM at the pre–B cell stage of development. This fact might contribute to the difficulty in eradicating the neoplastic clone with chemotherapy.

Biologically, the pathogenesis of most cases of FL grade 3B differs from that of FL grade 1 and 2 in lacking the BCL2/IGH@ but also differs from DLBCL in having a low incidence of BCL6 aberrations.[14] These data provide a biologic explanation for the greater curability of grade 3 FL with aggressive therapy, although some studies have not found support for this hypothesis. Differences in diagnostic criteria might account for this apparent discrepancy, and the correlation between grade 3A versus 3B and molecular alterations is imprecise. In light of these data, cytologic grading is assuming less importance in clinical trials and clinical practice. Evolution toward a molecularly defined classification of FL is a possibility for the future.

The phenomenon of localization of FL cells to isolated germinal centers within a lymph node has been termed in situ FL.[15] This pattern may be seen with FL at other sites of disease or may be the only manifestation of disease in some patients. The risk for progression in this latter group is not fully established, but if no other evidence of FL is seen at initial clinical evaluation, the likelihood of evolution to clinically significant FL is low. Indeed, this translocation can be found in the peripheral blood and lymphoid organs of healthy individuals and suggests that the *BCL2/IGH@* translocation is necessary but not sufficient for the development of FL.[16] "In situ FL" (also termed intrafollicular neoplasia) is a distinctive lesion and should be distinguished from partial involvement by FL.[15] In the true "in situ" lesion, clusters of B cells strongly positive for CD10 and BCL2 are localized to germinal centers in an otherwise reactive lymph node. It often represents an incidental finding in a lymph node biopsied for other reasons. The term "FL-like B-cells of unknown significance" was recently proposed for this lesion.[17]

The 2008 WHO classification recognizes other lymphomas of follicle center derivation that may resemble nodal FL but exhibit significant differences either clinically or biologically. These include pediatric FL, primary intestinal FL, and cutaneous lymphomas of follicle center cell derivation. Intestinal FL, most often presenting in the duodenum, is associated with the BCL2/IGH@ translocation but usually presents as isolated mucosal polyps with a low risk of dissemination.[18] Conversely, pediatric FL is often extranodal at presentation, usually grade 3B, and not associated with translocations of BCL2. At least some cases have been shown to have a different molecular pathogenesis.[19,20] These tumors are usually associated with a good prognosis, and in some patients, complete remissions may be

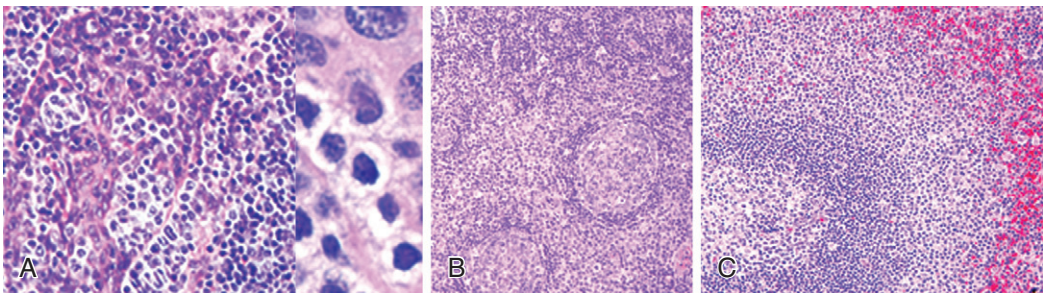

Figure 72-7 MARGINAL ZONE LYMPHOMA. Marginal zone lymphomas commonly occur at extranodal sites arising from mucosa-associated lymphoid tissue (MALT). MALT lymphomas typically infiltrate or invade into epithelial structures, resulting in "lymphoepithelial lesions" **(A).** They are composed of small- to intermediate-sized cells with abundant clear cytoplasms (**A,** *detail*). The normal lymph node does not have a marginal zone, but primary nodal marginal zone lymphomas (NMZL) can occur. They infiltrate the node in what would be a marginal zone pattern with an expansion of cells peripheral to mantle zone **(B).** The spleen does have a normal marginal zone, and this can give rise to a splenic marginal zone lymphoma (SMZL). Early on, these show expansion of the marginal zone areas **(C)** but later can become more diffuse, infiltrating the red pulp. In the case illustrated, the spleen weighed 1700 g.

obtained with either surgical excision or local radiation therapy. The pediatric variant of FL is more common in males than females.

Primary cutaneous follicle center lymphoma, which frequently lacks the *BCL2* translocation and BCL2 expression, is now considered by the WHO classification as a separate entity.[17] However, when BCL2 expression is detected, the possibility that this may represent a secondary site of involvement should be considered.

Extranodal Marginal Zone Lymphoma of Mucosa-Associated Lymphoid Tissue Type

Most lymphomas of marginal-zone derivation present in extranodal sites and have the histopathologic and clinical features identified by Isaacson and Wright as part of the spectrum of mucosa-associated lymphoid tissue (MALT) lymphomas. MALT lymphomas are characterized by a heterogeneous cellular composition that includes marginal-zone or centrocyte-like cells, monocytoid B cells, small lymphocytes, and plasma cells (Fig. 72-7, *A*). In most cases, large transformed cells are infrequent. Reactive germinal centers are nearly always present. When follicular colonization occurs, the process may simulate FL. Clonality is confirmed by molecular and or immunohistochemical studies.

MALT lymphomas have been described in nearly every anatomic site but are most frequent in the stomach, lung, thyroid, salivary gland, and lacrimal gland. Other less common sites of involvement include the orbit, breast, conjunctiva, bladder and kidney, and thymus gland. Widespread nodal involvement is infrequent, as is BM involvement. The clinical course is usually quite indolent, and many patients are asymptomatic. MALT lymphomas tend to relapse in other MALT-associated sites.

MALT lymphomas of the salivary gland and thyroid are usually associated with a history of autoimmune diseases. Helicobacter gastritis is frequent in most patients with gastric MALT lymphomas. Other infectious agents have been described in MALT lymphomas involving the skin *(Borrelia burgdorferi),* ocular adnexae *(Chlamydia psittaci),* and small intestine *(Campylobacter jejuni);* however, in this latter group, a causal relationship has not yet been demonstrated. Chronic antigen stimulation is critical to both the development of a MALT lymphoma and the maintenance of the neoplastic state. Indeed, in some cases, antibiotic therapy and the eradication of *Helicobacter pylori* have led to the spontaneous remission of gastric MALT lymphoma in cases lacking genetic aberrations.

By immunophenotype, MALT lymphomas are positive for B cell–associated antigens CD19, CD20, and CD22 but are negative for CD5 and CD10. The absence of cyclin D1 is useful in ruling out MCL, especially in intestinal disease. Rare cases of MALT lymphoma have been reported to be CD5 positive, and in some but not all instances, this has been associated with more aggressive disease.

MALT lymphomas also have several recurring cytogenetic abnormalities, including t(11;18)(q21;q21), t(1;14)(p22;q32), t(14;18)(q32;q21), t(3;14)(q27;q32), and t(3;14)(p14.1;q32), which are observed with variable frequency, often depending on the anatomic site. Although several genes are involved in these translocations, at least three of them—(t(11;18), t(1;14) and t(14;18)—share a common pathway, which leads to the activation of nuclear factor kappa-B (NFκB) and its downstream targets. By genome-wide DNA profiling integrated with GEP, differences were detected among the three different main types of marginal zone lymphomas, lending support to the current WHO classification, which separates these three entities.[21]

The WHO Clinical Advisory Committee recommended that the term *high-grade MALT* not be used for extranodal large cell lymphomas in a "MALT" site and in fact stated that this term should be avoided because of its ambiguity. The clinical significance of increased transformed cells is still uncertain. The putative cell of origin of MALT lymphoma is a post-germinal center B-cell.

Nodal Marginal Zone Lymphoma

Nodal marginal zone lymphoma (NMZL) is a primary nodal disease, which resembles other marginal zone lymphomas, extranodal or splenic types. These patients often present with BM involvement and tend to have a more aggressive clinical course than those with extranodal MALT. The neoplastic proliferation is polymorphous and composed of monocytoid B cells and plasmacytoid cells with interspersed large blastlike cells. There is an expansion of the marginal zone area, often with preservation of the nodal architecture (Fig. 72-7, *B*). The mantle zone may be intact, attenuated, or effaced. The immunophenotype is similar to other MZL, that is, CD20 positive, CD10 negative, and CD5 negative, with variable expression of IgD (weak to negative). Because there are no precise immunophenotypic or genotypic markers of NMZL, the diagnosis is sometimes one of exclusion. The differential diagnosis with LPL may be problematic. A variant of nodal MZL occurs in children; these cases shows a striking male predominance, present with localized disease, and can be managed with local therapies.[22]

Splenic Marginal Zone Lymphoma

Splenic marginal zone lymphomas (SMZLs) present in adults and are slightly more frequent in women than men. The clinical presentation is splenomegaly, usually without peripheral lymphadenopathy. The

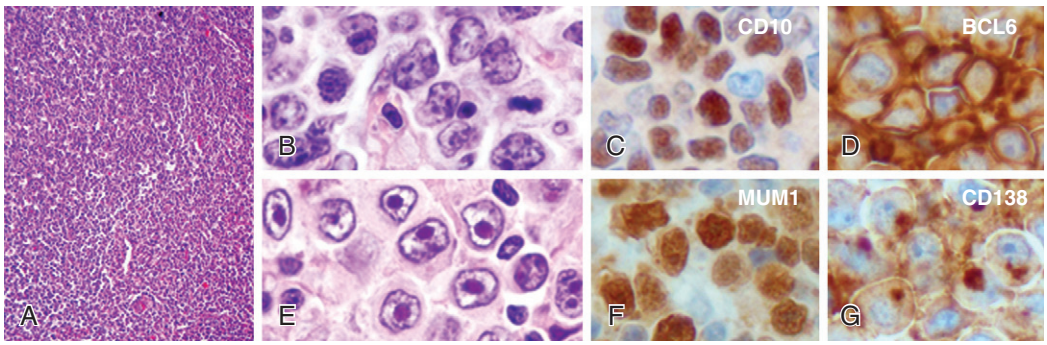

Figure 72-8 DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL). The low power illustration demonstrates the diffuse nature of the process **(A).** At high power **(B),** there are sheets of large cells. Those with a vesicular nuclear chromatin and variable numbers of nucleoli along the nuclear membrane are referred to as centroblasts. These typically have a germinal center gene expression profile and a germinal center immunophenotype with expression of BCL6 and CD10 (**C** and **D**). Those cases composed of large cells with a single prominent nucleolus **(E)** are called immunoblastic and commonly have an activated B-cell (ABC) gene expression profile and an ABC phenotype with expression of Mum-1, CD138 (**F** and **G**), and IFR-4. The correlation of morphology and immunophenotype is not always exact.

majority of patients have BM involvement, but there is usually only a modest lymphocytosis, with elevations in the lymphocyte count usually less than that seen in CLL. Some evidence of plasmacytoid differentiation may be seen, and patients may have a small M component. The abundant pale cytoplasm evident in tissue sections may also be seen in blood smears. The course is indolent, and splenectomy may be followed by a prolonged remission.

Histologically, the spleen shows expansion of the white pulp but usually some infiltration of the red pulp is present as well (see Fig. 72-7, *C*). A characteristic biphasic pattern in the neoplastic white pulp has been described, with the neoplastic cells surrounding regressed follicles. The immunophenotype of these cells resembles that of other marginal-zone B-cell lymphomas; however, IgD expression is more frequently observed. Progression to DLBCL can be seen.

Although the molecular pathogenesis of SMZL has not been delineated, a frequent cytogenetic alteration involving deletions of the region 7q(22-32) has been reported.[23] Studies of the Ig variable genes have also revealed the presence of mutations suggesting a post-follicular origin, but variations in this profile have been observed. The differential diagnosis of SMZL includes other unspecified B-cell lymphomas of the spleen, including splenic lymphoma with villous lymphocytes (SLVL), and hairy cell variant. The latter have been grouped together under splenic B-cell lymphoma/leukemia unclassifiable, and the interrelationship among these disorders is not fully resolved.

Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

Diffuse large B-cell lymphoma is one of the more common subtypes of NHL, representing up to 40% of cases. It has an aggressive natural history but responds well to chemotherapy. The complete remission rate with modern regimens is 75% to 80%, with long-term disease-free survival approaching 50% or more in most series. This lymphoma may present in lymph nodes or in extranodal sites. Frequent extranodal sites of involvement include bone, skin, thyroid, gastrointestinal tract, and lung.

Diffuse large B-cell lymphoma represents one of the most heterogeneous categories in the WHO classification, and attempts to identify prognostic groups based on morphology and phenotype have shown limited usefulness and reproducibility (see box on Varied Basis for the Recognition of Diverse Entities Among Aggressive B-Cell Neoplasms). To address these issues, DLBCLs were among the first cases to be analyzed by cDNA array technology and more recently also by genome-wide analysis.[24] By GEP, three groups were identified based on the differential expression of a large set of genes, namely germinal center–like group (GCB), activated B cell–like group (ABC), and primary mediastinal (thymic) large B-cell lymphoma (PMBL). The expression profile reflects a corresponding non-neoplastic counterpart, which shares similarity with germinal center B cells (GCB), and postgerminal center B cells (ABC). A unique signature was identified by GEP in PMBL, which shared similarities with CHL cell lines, including constitutive activation of the NFκB and recurrent gains and amplification of c-Rel. More recently, frequent genetic defects have been identified in the BCR-signaling and NFkB pathways in the ABC subtype providing new insight in the pathogenesis of DLBCL and new potential therapeutic targets.[25,26a] Recurrent mutations in the GCB type of DLBCL appear to target histone-modifying genes.[24,26b] Somatic mutations in *EZH2* also have been identified in FL, another tumor of germinal center derivation.

Diffuse large B-cell lymphomas are composed of large, transformed lymphoid cells with nuclei at least twice the size of a small lymphocyte (Fig. 72-8). The nuclei generally have vesicular chromatin, prominent nucleoli, and basophilic cytoplasm, resembling the centroblasts of the normal germinal center. The immunoblastic variant is characterized by cells with prominent central nucleoli and abundant deeply staining cytoplasm. Although there is no absolute correlation between morphology and GEP, the majority of centroblastic DLBCL falls into the GCB group and the majority of immunoblastic into the ABC group.

Algorithms based on immunophenotype have been proposed as surrogates for cDNA microarray using CD10/BCL-6 positivity for GCB and Mum-1/IRF-4 for ABC with the addition of BCL-2 in

Varied Basis for the Recognition of Diverse Entities Among Aggressive B-Cell Neoplasms

Cell of Origin, in Part as Determined by Gene Expression Profiling
- Activated B cell versus germinal center B cell
- Thymic B cell of PMBL

Clinical Factors
- Anatomic site (e.g., CNS, mediastinum, intravascular)
- Advanced age, background of chronic inflammation

Etiologic Factors
- EBV, HHV-8

Molecular Pathogenesis
- *BCL6, C-MYC, ALK, BCL2, MYD88* (translocations, amplification, mutation)

ABC, Activated B cell; *CNS,* central nervous system *GCB,* germinal center B cells; *PMBL,* primary mediastinal large B-cell lymphoma.

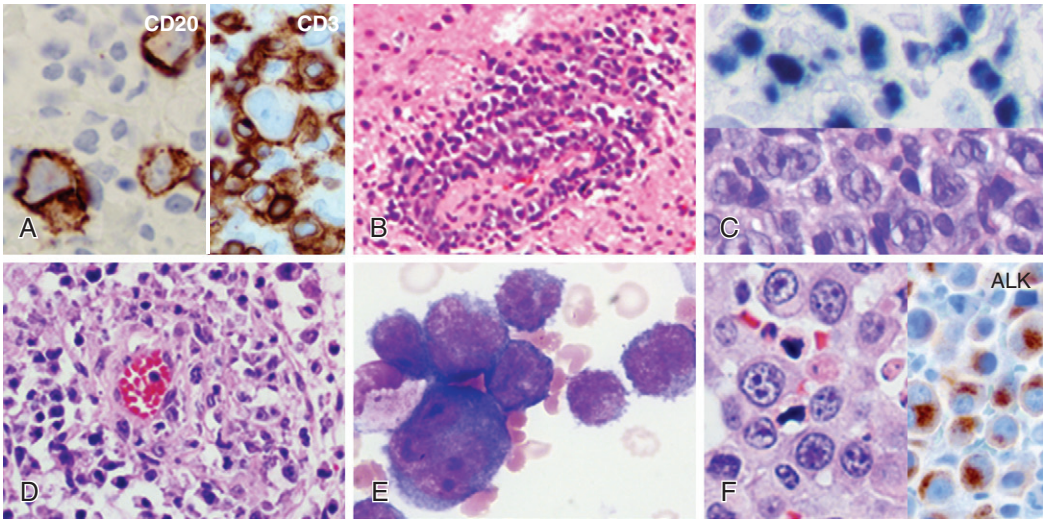

Figure 72-9 DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL) VARIANTS AND SUBTYPES. T-cell/histiocyte-rich large B-cell lymphoma is illustrated in **A,** where a CD20 immunostain *(right)* identifies scattered large B cells, which are associated with a prominent background of small reactive T cells (CD3; *left*). Sometimes there are numerous histiocytes in the background or an admixture of reactive T cells and histiocytes. Primary DLBCL of the central nervous system usually shows a perivascular distribution (**B**). Epstein-Barr virus (EBV)–positive DLBCL of the elderly can have variable morphologic features sometimes with a polymorphic mixture of large cells and small lymphocytes and plasma cells. Sometimes they can be monomorphic and composed of large cells, which are positive for EBV-encoded RNA (EBER) (**C,** *bottom* and *top*). Lymphomatoid granulomatosis **(D)** also has a perivascular distribution and is composed of a mix of malignant large EBV-positive B cells and reactive T cells. Primary effusion lymphoma usually is diagnosed from cytologic preparations **(E)** and by flow cytometric and molecular techniques. Although the tumor cells do not generally form masses, recent reports have identified a solid variant. Plasmablastic B-cell lymphoma is quite rare and can show ALK positivity as a consequence of a translocation of *ALK* **(F).**

combination with IPI and may improve the stratification of DLBCL. However, there is as yet no consensus for the best model to address the heterogeneity of DLBCL, and the correlation with GEP has been questioned.[17]

Diffuse Large B-Cell Lymphomas: Other Variants and Subtypes

The spectrum of aggressive B-cell lymphomas has broadened in recent years, incorporating new entities based on unique clinical features such as age or anatomic site, viral pathogenesis (EBV, human herpesvirus 8 [HHV-8]), or distinctive pathological features.[27]

T-cell or histiocyte-rich large B-cell lymphoma (THRLBCL) is now considered a distinct clinical pathologic entity rather than a morphologic variant of DLBCL (see Fig. 72-9, *A*). It has been associated with aggressive clinical behavior and often presents in younger patients than typical DLBCL with advanced stage and BM involvement. The relevance of the microenvironment and recruitment mechanism of the inflammatory cells, which are the main histological component, has been the focus of recent studies.[28]

The WHO classification recognizes that some lymphomas arising in certain anatomic sites may have distinctive features both clinically and biologically. Among these are *primary DLBCL of the central nervous system (CNS)* and *primary cutaneous DLBCL, leg type.* Primary DLBCL of the CNS (see Fig. 72-9, *B*) has some distinctive features based on GEP and shares some similarities with DLBCL arising in other immune privileged sites such as the testis.[17] Primary cutaneous DLBCL, leg type, has a GEP resembling the ABC type of DLBCL, presents most often in elderly women, and generally has an aggressive clinical course. As with nodal DLBCL, Bcl-2 expression is an adverse prognostic factor.

There are several EBV-positive B-cell lymphoproliferations that are often grouped with DLBCL. *EBV-positive DLBCL of the elderly* is a provisional entity in the 2008 WHO classification.[29] It appears to develop as a consequence of decreased immune surveillance. The morphological spectrum is broad and includes polymorphous and more monomorphic tumors (see Fig. 72-9, *C*). Most cases have an aggressive clinical course and should be distinguished from atypical hyperplasia associated with EBV and lesions with a self-limited course, such as EBV-positive mucocutaneous ulcer.

Lymphomatoid granulomatosis is an EBV-positive B-cell lymphoproliferative disorder (LPD) associated with an inflammatory background rich in T cells (Fig. 72-9, *D*). The lung is nearly always involved, with the skin, kidney, liver, and brain being frequently affected as well. *DLBCL associated with chronic inflammation* was first described in association with chronic pyothorax but now has been associated with EBV-driven large B-cell proliferations in diverse clinical settings, usually associated with a confined anatomic space and a background of chronic inflammation. These cases appear to have a good prognosis if successfully resected.

Several LPDs are associated with HHV-8/Kaposi sarcoma–associated herpesvirus. These include *primary effusion lymphoma (PEL)* and *multicentric Castleman disease (MCD),* as well as lymphomas arising in the context of MCD. The cells of PEL are usually coinfected with EBV, and the disease is most often diagnosed in the setting of HIV infection and immunosuppression. Although pleural or peritoneal effusions are most common (Fig. 72-9, *E*), extracavitary PEL can present as a tumor mass, usually in extranodal sites. PEL has a phenotype resembling that of terminally differentiated B cells (i.e., plasmablastic).

Two other lymphomas with a plasmablastic phenotype include *plasmablastic lymphoma (PBL)* and *ALK-positive large B-cell lymphoma*. PBL is usually positive for EBV, most often extranodal, and associated with immunosuppression from either HIV infection or advanced age. Recent studies have identified a high incidence of MYC translocations in PBL.[30] ALK-positive large B-cell lymphomas show overexpression of ALK (Fig. 72-9, *F*), usually as a consequence of translocation involving the ALK gene. They mainly affect older individuals but can occur at any age. Interestingly, IgA is most often expressed.

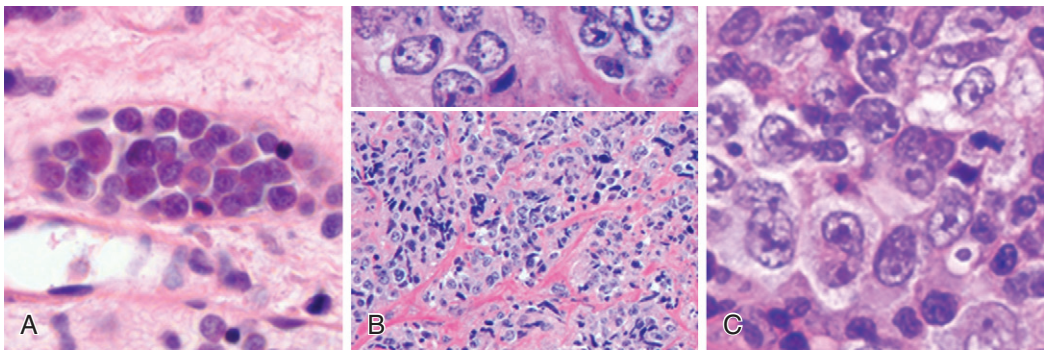

Figure 72-10 DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL) VARIANTS (INTRAVASCULAR, MEDIASTINAL, UNCLASSIFIABLE). In intravascular lymphoma, also known as angiotropic lymphoma, the large B cells are confined to the inside of vessels **(A).** Paradoxically, they do not spread to the blood. Primary mediastinal (thymic) large B-cell lymphoma typically shows sclerosis and large B cells immeshed in the fibrosis (**B,** *top* and *bottom*). An unclassifiable type of lymphoma has features intermediate between large B-cell lymphoma and Hodgkin lymphoma. In the case illustrated **(C),** the male patient presented with a mediastinal mass. The cells were $CD30^{+}$ and only variably positive for CD45 as in Hodgkin lymphoma, but they were strongly and uniformly positive for CD20 and PAX5. They also strongly expressed the B-cell transcription factors OCT2 and BOB1.

Intravascular Large B-Cell Lymphoma

Intravascular large B-cell lymphoma is a rare form of DLBCL characterized by the presence of lymphoma cells only in the lumens of small vessels, particularly capillaries (Fig. 72-10, *A*). These cells are nearly always of B-cell phenotype, often with aberrant expression of CD5. The tumor cells are large, with vesicular nuclei and prominent nucleoli, resembling centroblasts or immunoblasts. Lymph node involvement is rare, and the tumor presents in extranodal sites, most readily diagnosed in the skin. Neurologic symptoms associated with plugging of small vessels in the CNS are common. The disease is often not diagnosed until autopsy because of the lack of definitive radiologic or clinical evidence of disease and diverse symptomatology.

Primary Mediastinal (Thymic) Large B-Cell Lymphoma

Primary mediastinal large B-cell lymphoma has emerged in recent years as a distinct clinicopathologic entity, typically arising in young women, with a peak incidence in the fourth decade of life. Patients present with a mediastinal mass with frequent superior vena caval syndrome. Regional lymph nodes may be involved, but spread to distant nodal sites is uncommon. Frequent extranodal sites of involvement, particularly at relapse, include the liver, kidneys, adrenal glands, ovaries, gastrointestinal tract, and CNS.

Histologically, PMBL is characterized by fine compartmentalizing sclerosis, and large lymphoid cells with abundant pale cytoplasms (Fig. 72-10, *B*). An origin from medullary thymic B cells has been proposed. The cells express CD20 and CD79a but do not express surface Ig. Recently, expression of the MAL gene has been detected in PMBL and not in other DLBCLs.[31] PMBL usually lacks rearrangement for BCL2, BCL6; however, *REL* amplification is a common feature. A common cytogenetic abnormality seen in approximately 50% of cases includes gains in 9p, which may be associated with amplification of Janus kinase 2 *(JAK2).* Recently, GEP studies have found that PMBL bears a distinct molecular signature that differs from that of other DLBCLs and shares features of CHL.

B-Cell Lymphoma, Unclassifiable, With Features Intermediate Between Diffuse Large B-Cell Lymphoma and Classical Hodgkin Lymphoma

A new aspect of the 2008 WHO classification is the inclusion of borderline categories, one of which manifests features intermediate between DLBCL, especially PMBL, and CHL (see Fig. 72-10, *C*). These tumors are sometimes referred to as *gray zone lymphomas*. A close relationship between PMBL and CHL was supported by GEP.[31] TRAF1 expression and *c-REL* amplification also were seen in both types of neoplasms and could be detected with suitable immunohistochemical studies.

Gray zone lymphomas are more common in males than females, present with bulky mediastinal masses, and appear to have a more aggressive clinical course than PMBL or CHL. A recent study using methylation profiling identified gray zone lymphomas as having a signature distinct from both CHL and PMBL. However, by fluorescence in situ hybridization, gray zone lymphomas, PBMCL, and CHL share a number of common cytogenetic aberrations, including gains at 2p16.1 (*REL/BCL11A* locus), 9p24.1 *(JAK2/PDL2)* and rearrangements of 16p13.13 (*CIITA).* It is not clear how these patients should be approached therapeutically, but they appear to benefit from combine modality therapy (systemic chemotherapy and radiation).

Burkitt Lymphoma

Burkitt lymphoma (BL) is most common in children and accounts for up to one-third of all pediatric lymphomas in the United States. It is the most rapidly growing of all lymphomas, with 100% of the cells in cell cycle at any time. It usually presents in extranodal sites. In non-endemic regions, such as the United States, frequent sites of presentation are the ileocecal region, ovaries, kidneys, or breasts. Jaw presentations, as well as involvement of other facial bones, are common in African or endemic cases and are seen occasionally in nonendemic regions. BM involvement is a poor prognostic sign.

Burkitt lymphoma is one of the more common tumors associated with human immunodeficiency virus (HIV). It can present at any time during the clinical course. In some patients with HIV infection, BL may be the initial acquired immunodeficiency syndrome (AIDS)–defining illness.

The pathogenesis of BL is related to the translocations involving the *MYC* oncogene, which are seen in virtually 100% of cases and often constitute the sole karyotypic abnormality. Most cases involve the *IGH@* gene on chromosome 14 and less frequently the light-chain genes on chromosomes 2 and 22.

African BL occurs in regions endemic for malaria, and it has been postulated that the pathogenesis appears similar to that seen with HIV infection; recent GEP data also support a common pathogenetic mechanism.[32]

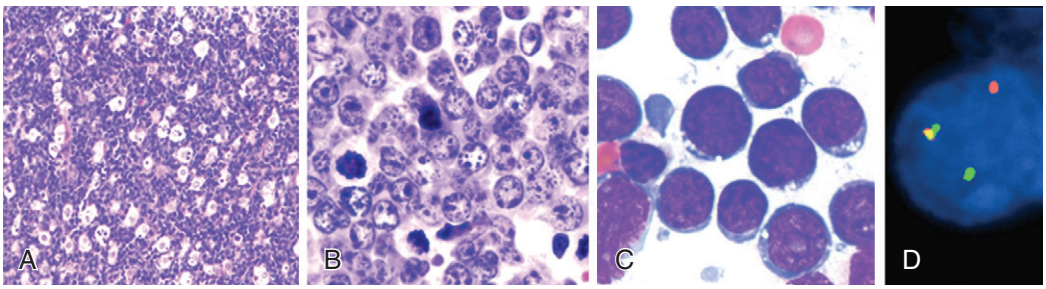

Figure 72-11 BURKITT LYMPHOMA (BL). At low power, BL gives a classic "starry sky" appearance because of numerous histiocytes or tingible body macrophages with clear cytoplasm *(stars),* in a background of darkly stained tumor cells **(A).** At high power, the cells exhibit a very high mitotic rate and are intermediate in size with an almost stippled nuclear chromatin **(B).** On a Wright-stained touch preparation or in the blood or bone marrow aspirate, the cells also have a characteristic appearance with deep blue cytoplasm typically with vacuoles **(C).** Fluorescence in situ hybridization with a probe that spans *MYC* will show a break-apart signal **(D)** indicating that the *MYC* has translocated to a partner chromosome.

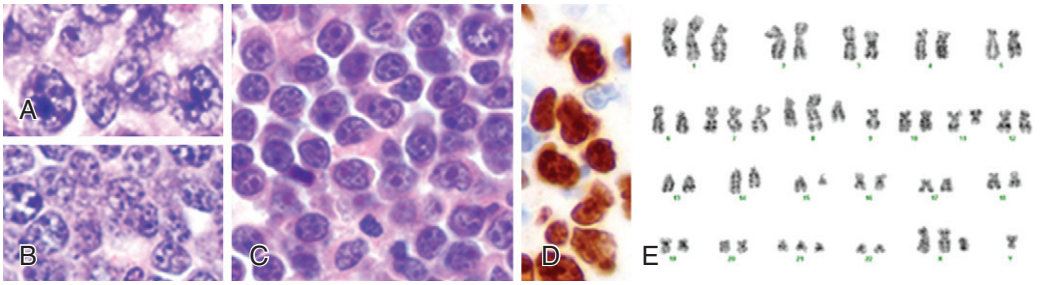

Figure 72-12 B-CELL LYMPHOMA, UNCLASSIFIABLE WITH FEATURES INTERMEDIATE BETWEEN DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL) AND BURKITT LYMPHOMA (BL). Examples of DLBCL **(A)** and BL **(B)** are for comparison. In **C,** the lymphoma cells are intermediate in size and not as large as the DLBCL but without the typical characteristics of BL cells. The cells had a high Ki67 rate **(D)** and a B-cell phenotype with CD10 and BCL2 expression (not shown). The karyotype had a t(14;18) as in follicular lymphoma but was complex and involved the *MYC* gene in multiple translocations **(E).** The karyotype was as follows: 51,XY,+X,+1,dup(1)(q32q44),der(1)del(1)(p21p36.3)dup(1)(q32q44),t(6;8)(p21.1;q24.1),+7,+del(?8) (p11.2p23),der(8)i(8)(q10)t(8;11)(q24.1;q13),-9,der(11)t(8;11)(q24.1;q13), t(14;15)(q32;q15), t(14;18)(q32;q21.3),+21,+mar[13]/46,XY[1]. *(The karyotype was kindly provided by Dr. Yanming Zhan of Northwestern University).*

Epstein-Barr virus is closely linked to BL in endemic regions but is less frequently seen (15%-20%) in sporadic cases. In other regions characterized by low socioeconomic status and EBV infection at an early age, BL is often EBV positive in the range of 50% to 70%. These data support the concept that the EBV is a cofactor for the development of BL. Cytologically, BL is monomorphic (Fig. 72-11). The cells are medium in size with round nuclei, moderately clumped chromatin, and multiple (two to five) basophilic nucleoli. The cytoplasm is deeply basophilic and moderately abundant. These cells contain cytoplasmic lipid vacuoles, which are probably a manifestation of the high rate of proliferation and high rate of spontaneous cell death. The starry sky pattern characteristic of BL is a manifestation of the numerous benign macrophages that have ingested karyorrhectic or apoptotic tumor cells.

Burkitt lymphoma has a mature B-cell phenotype. The cells express CD19, CD20, CD22, CD79a, and monoclonal surface Ig, nearly always IgM. CD10 is positive in nearly all cases, and CD5, CD23, and BCL-2 are consistently negative.

B-Cell Lymphoma, Unclassifiable, With Features Intermediate Between Diffuse Large B-Cell Lymphoma and Burkitt Lymphoma

Historically, it has been difficult for pathologists to distinguish some DLBCL with a very high growth fraction from BL with atypical cytology. In addition, there are cases that have a molecular GEP of BL but carry additional cytogenetic abnormalities, most often involving *BCL2* or *BCL6*. These double- and triple-hit lymphomas have a very aggressive clinical course. To recognize and delineate these cases, this borderline category was created in the 2008 WHO classification (Fig. 72-12). However, it should not be used for otherwise typical DLBCL with a *MYC* translocation. The clinical impact of MYC overexpression in DLBCL has not been fully resolved; in some series, has been associated with a more aggressive clinical course, but in most such cases in adults, C-*MYC* translocation occurs in the setting of multiple genetic aberrations.[27] This unclassified category also should not be used for cases of BL with atypical cytologic features, which are retained under the heading of BL and have a better prognosis when treated appropriately.

T-CELL AND NATURAL KILLER CELL LYMPHOMAS

Overview of the Classification of T-Cell Neoplasms

Although the definition of precursor T-cell or lymphoblastic neoplasms is straightforward, the classification of peripheral T-cell lymphomas has been controversial. These are uncommon, representing fewer than 15% cases of NHL. Most previously published classification schemes for the malignant lymphomas in the United States or Europe have been based on B-cell malignancies because these are far more common than their T-cell counterparts. T-cell and NK cell lymphomas show significant variation in incidence in different geographic regions and racial populations.

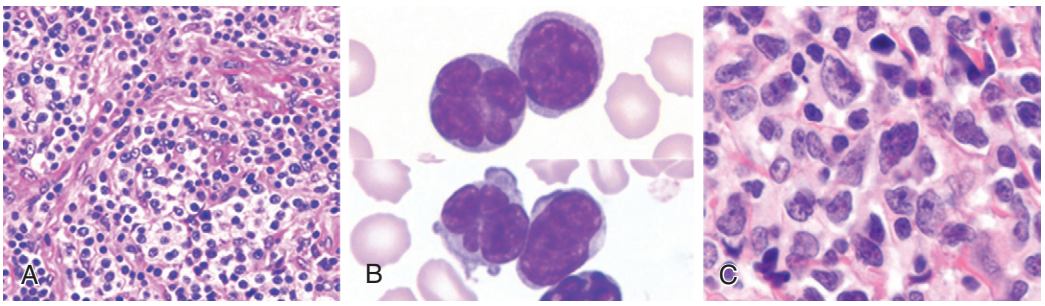

Figure 72-13 T-CELL LYMPHOMA. In angioimmunoblastic T-cell lymphoma (AILT), the lymph node shows effacement because of a vascular proliferation of post-capillary venules and clustered large cells with clear cytoplasms in the background of plasma cells, immunoblasts, and small lymphocytes **(A).** The peripheral blood in adult T-cell leukemia/lymphoma (ATLL) has classic "flower-cells" **(B).** Peripheral T-cell lymphoma (PTCL) is heterogeneous, but typically there is a mixture of small and large neoplastic T cells **(C).**

Natural Killer Cell and T-Cell Subsets and the Classification of Peripheral T-Cell and Natural Killer Cell Neoplasms

Innate Immune System	*Adaptive Immune System*
Does not require antigen sensitization	Characterized by specificity and memory
NK cells, NK/T cells, γ-δ T cells	Effector and memory T cells
Cell-mediated cytotoxicity	Act principally through cytokines and chemokines
Mainly cutaneous and other extranodal sites	Mainly nodal lymphomas
Children and adults	More often in adults

The classification of T-cell and NK cell neoplasms proposed by the WHO emphasizes a multiparameter approach, integrating morphologic, immunophenotypic, genetic, and clinical features. Clinical features play particular importance in the subclassification of these tumors, partly because of the lack of specificity of other parameters (see box on Natural Killer and T-Cell Subsets and the Classification of Peripheral T-Cell and Natural Killer Cell Neoplasms).

In contrast to B-cell lymphomas, specific immunophenotypic profiles are not associated with most T-cell lymphoma subtypes. Although certain antigens are commonly associated with specific disease entities, these associations are not entirely disease specific. Presently, specific genetic features have not been identified for many of the T-cell and NK cell neoplasms, although there are few exceptions.

Angioimmunoblastic T-Cell Lymphoma

Angioimmunoblastic T-cell lymphoma (AILT) was initially proposed as an abnormal immune reaction or form of atypical lymphoid hyperplasia with a high risk of progression to malignant lymphoma. Because the majority of cases show clonal rearrangements of T-cell receptor genes, it is now regarded as a variant of T-cell lymphoma. The median survival is generally less than 5 years.

Angioimmunoblastic T-cell lymphoma presents in adults; most patients have generalized lymphadenopathy, hepatosplenomegaly, skin rash, and prominent constitutional symptoms. They also usually have polyclonal hypergammaglobulinemia and other hematologic abnormalities such as Coombs-positive hemolytic anemia. Rituximab has been used in some recent clinical trials in an attempt to control some of the effects of B-cell hyperactivity in this disease. Patients may also show evidence of immunodeficiency with recurrent opportunistic infections that may ultimately lead to their demise.

The nodal architecture is generally effaced, but peripheral sinuses are often open and even dilated. At low power, there is usually a striking proliferation of high endothelial venules (HEV) with prominent arborization (see Fig. 72-13, *A*). Follicles are typically regressed, but there is a proliferation of dendritic cells around HEV. The atypical T cells have clear cytoplasms and are associated with small lymphocytes, immunoblasts, plasma cells, and histiocytes. The abnormal cells are usually positive for CD3, CD4, CD10, and CD279 (PD-1), a phenotype characteristic of follicular T-helper cells. This relationship is also confirmed by recent GEP data. CXCL13, a chemokine involved in B-cell trafficking into the germinal centers, is also expressed in AILT.

Epstein-Barr virus–positive large B-cell blasts are nearly always present in the background, and progression to EBV-positive DLBCL has been reported in rare cases. Atypical B-cell proliferations that are negative for EBV also occur, presumably related to the T-helper follicular function of the neoplastic cells in promoting the activation and migration of bystander B cells. However, the exact role of EBV in AILT remains uncertain.

Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma (ATLL) is a distinct clinicopathologic entity associated with the retrovirus HTLV-I, which is found clonally integrated in the T cells. HTLV-1 infection is endemic in Southwestern Japan and in the Caribbean basin. The disease has a long latency, and affected individuals usually are exposed to the virus very early in life. The virus may be transmitted in breast milk and through exposure to blood and blood products. The cumulative incidence of ATLL is estimated to be 2.5% among HTLV-1 carriers.

The median age of affected individuals is 45 years. Patients may present with leukemia or generalized lymphadenopathy. Other clinical findings include lymphadenopathy, hepatosplenomegaly, lytic bone lesions, and hypercalcemia. Cutaneous involvement is seen in the majority of patients. The acute form of the disease is associated with a poor prognosis and a median survival of less than 2 years. Complete remissions may be obtained, but the relapse rate is nearly 100%.

Chronic and smoldering forms of the disease are seen less commonly and are associated with minimal lymphadenopathy. The predominant clinical manifestation is skin rash, with only small numbers of atypical cells in the peripheral blood.

The cytologic spectrum of ATLL is extremely diverse (Fig. 72-13, *B*). The cells are often markedly polylobated and have been referred to as flower cells. Peripheral blood involvement is very common but often in the absence of BM disease. Immunophenotypically, the neoplastic cells are positive for mature T-cell antigens, such as CD2, CD3, and CD5; they are typically CD4/CD25 positive, a phenotype that resembles regulatory T (Tregs) cells. Some cases express FoxP3 but usually in a minority of tumor cells. The function of the tumor cells as Treg cells may correlate with the associated immunodeficiency.

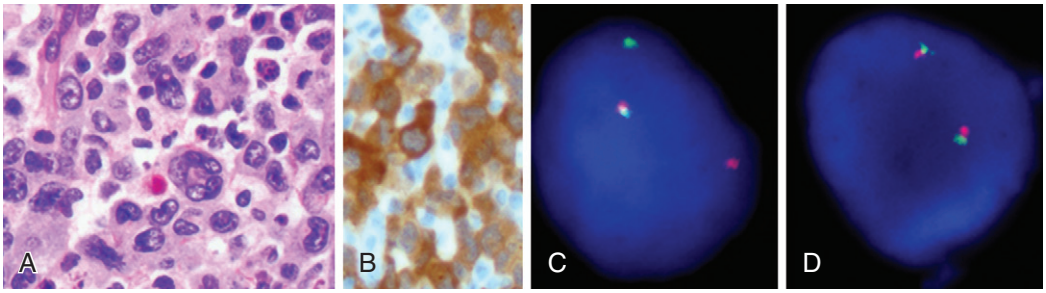

Figure 72-14 T-CELL LYMPHOMA: ANAPLASTIC LARGE CELL LYMPHOMA (ALCL). ATCL is characterized by a mix of pleomorphic malignant large T cells **(A),** which include "wreath cells" *(center)* and "hallmark cells" *(bottom right).* **B,** The presence of ALK staining with nuclear and cytoplasmic localization *(right)* is associated with the t(2;5). A translocation of ALK can be identified with a break-apart probe that spans *ALK* but is split when *ALK* is translocated to one of a number of partners. A cell with a translocated *ALK* is pictured in **C** and a normal cell in **D**.

Peripheral T-Cell Lymphomas, Not Otherwise Specified

Peripheral T-cell lymphomas, not otherwise specified (PTCL, NOS) is a diagnosis of exclusion and is admittedly a heterogeneous category with most cases being nodal in origin. Therefore, not unexpectedly, the cytologic spectrum is very broad[33] (Fig. 72-13, *C*). An inflammatory background is frequent, consisting of eosinophils, plasma cells, and histiocytes. If the epithelioid histiocytes are numerous and clustered, the neoplasm fulfils the criteria for the lymphoepithelioid cell variant of PTCL. The T-zone variant is composed of small- to medium-sized cells that preferentially involve the paracortical regions of the lymph node.

There is also a rare follicular variant composed of TFH cells that are restricted to the lymphoid follicles.

Clinically, PTCL, NOS most often presents in adults with generalized lymphadenopathy, hepatosplenomegaly, and frequent BM involvement. Constitutional symptoms, including fever and night sweats, are common, as is pruritus. The clinical course is aggressive, although complete remissions may be obtained with combination chemotherapy. However, the relapse rate is higher than in aggressive B-cell lymphomas, including DLBCL.

PTCL, NOS, as defined in the WHO classification, remains heterogeneous. It is likely that individual clinicopathologic entities will be delineated in the future from this broad group of malignancies. Thus far, immunophenotypic criteria have not been helpful in delineating subtypes. Most cases have a mature T-cell phenotype and express one of the major subset antigens: CD4 > CD8. These are not clonal markers, and antigen expression can change over time. Loss of one of the pan T-cell antigens (CD3, CD5, CD2, or CD7) is seen in 75% of cases, with CD7 most frequently being absent. GEP studies have shown some cases with a profile resembling AILT. Cases with a high proliferation signature appear to have a more aggressive clinical course, but GEP has not led to the delineation of distinctive subtypes as independent entities.

Anaplastic Large Cell Lymphoma, ALK Positive

Anaplastic large cell lymphoma (ALCL) is characterized by pleomorphic or monomorphic cells, which have a propensity to invade lymphoid sinuses (Fig. 72-14). Because of the sinusoidal location of the tumor cells and their lobulated nuclear appearance, this disease when first observed was suspected to be of histiocytic origin. A consistent feature is the strong expression of CD30 antigen, a diagnostic hallmark. However, CD30 expression is not specific for ALCL and can be seen in a variety of conditions, of course, including CHL. Systemic ALCL is associated with a characteristic chromosomal translocation, t(2;5)(p23;q35), involving *NPM/ALK* genes, respectively. A number of variant translocations have been identified that involve partners other than *NPM*. All lead to overexpression of ALK, although the cellular distribution of *ALK* varies according to the gene partner.

The cells of classical ALCL have large, often lobulated nuclei with small basophilic nucleoli, so-called hallmark cells. The cytoplasm is usually abundant and amphophilic, and there are distinct cytoplasmic borders. A prominent Golgi region is generally visible. Small cell and lymphohistiocytic variants constitute part of the entity and appear to be associated with a more aggressive clinical course.[34]

The cells exhibit an aberrant phenotype with loss of many of the T cell–associated antigens. Both CD3 and CD5 are negative in more than 50% of cases. CD2 and CD4 are positive in the majority of cases. CD8 is usually negative. ALCL cells, despite the CD4-positive/CD8-negative phenotype, exhibit positivity for the cytotoxic-associated antigens TIA-1, granzyme B, and perforin. In addition, clusterin is generally present in ALCL and represents another useful diagnostic marker. By molecular studies, in most of the cases, a T-cell receptor rearrangement is found, confirming a T-cell origin.

Anaplastic large cell lymphoma is most common in children and young adults, and a marked male predominance is noted. Although most patients present with nodal disease, a high incidence of extranodal involvement has been reported (involving skin, bone, and soft tissue). Approximately 75% of cases present with advanced stage and systemic symptoms. Although these lymphomas have an aggressive natural clinical history, they respond well to chemotherapy. Overall survival and disease-free survival are significantly better among ALK-positive than ALK-negative cases. Both ALK-positive and -negative ALCL have better prognoses than other PTCLs, with a plateau in the survival curve seen in both groups.[35]

Anaplastic Large Cell Lymphoma, ALK Negative (Provisional Entity)

It has been controversial whether ALCL negative for ALK is a separate entity or part of the spectrum of PTCL, NOS. Part of the controversy relates to the lack of absolute criteria to recognize these cases. They should be morphologically and phenotypically similar to ALK-positive ALCL, with strong CD30 expression and a cytotoxic phenotype. They occur in an older age group than the ALK positive, and as already noted, appear to have a better prognosis than other PTCL, NOS.

Primary Cutaneous Anaplastic Large Cell Lymphoma

The primary cutaneous form of ALCL is closely related to lymphomatoid papulosis and differs clinically, immunophenotypically, and at the molecular level from the systemic form. Lymphomatoid papulosis and cutaneous ALCL are part of the spectrum of CD30-positive cutaneous T-cell lymphoproliferative diseases. Small lesions are likely to regress. Patients with large tumor masses may develop disseminated disease with lymph node involvement. However,

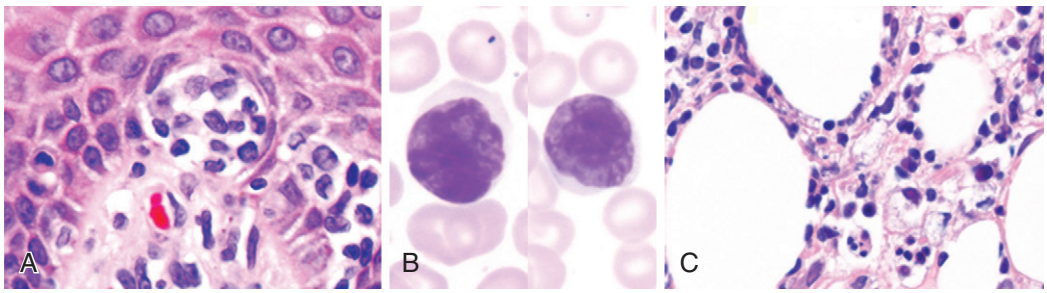

Figure 72-15 T-CELL LYMPHOMA: MYCOSIS FUNGOIDES/SÉZARY SYNDROME AND SUBCUTANEOUS PANNICULITIS-LIKE T-CELL LYMPHOMA (SPTCL). In mycosis fungoides, there is a dermal infiltrate with some malignant T cells infiltrating into the epithelium (Pautrier microabscesses) **(A).** Sézary cells with convoluted nuclear folding are seen in **B**. The peripheral nuclear outline is fairly rounded, but the internal nuclear detail shows complex nuclear folding giving rise to a convoluted and cerebriform look. A case of SPTCL is illustrated and shows an abnormal lymphoid infiltrate in the subcutaneous fat **(C).** This is associated with hemophagocytosis *(bottom center)* and necrosis.

primary cutaneous ALCL is a more indolent disease than other T-cell lymphomas of the skin. Because the skin nodules may show spontaneous regression, usually a period of observation is warranted before the institution of any chemotherapy. Cutaneous ALCL is CD30 positive but ALK negative, lacking translocations involving the *ALK* gene. However, recent studies have identified translocations of the *IRF4* gene in cutaneous ALCL.[36]

Mycosis Fungoides and Sézary Syndrome

Mycosis fungoides and Sézary syndrome are now regarded as separate diseases but are closely related and often considered together from a clinical and biologic standpoint.[37] Both are primary cutaneous T-cell malignancies derived from mature $CD4^+$ skin-homing T cells. Skin involvement may be manifested as multiple cutaneous plaques or nodules (Fig. 72-15, *A*). Sézary syndrome is characterized by erythroderma and a leukemic phase.[38] Lymphadenopathy is usually not present at presentation and, when identified, is associated with a poor prognosis. In early stages, enlarged lymph nodes may only show dermatopathic changes (category I). If malignant cells are present in significant numbers and are associated with architectural effacement (category II or III), the prognosis is significantly worse.

Cytologically, the small cells of mycosis fungoides demonstrate cerebriform nuclei with clumped chromatin, inconspicuous nucleoli, and sparse cytoplasm. Epidermotropism is usually a prominent feature. Sézary syndrome presents with exfoliative erythroderma and circulating cerebriform lymphocytes known as Sézary cells (Fig. 72-15, *B*). The typical phenotype is $CD2^+$, $CD3^+$, $CD5^+$, $CD4^+$, and $CD8^-$. However, CD8-positive variants of mycosis fungoides have been described and are more common in children. The absence of CD7 is a constant feature but may also be seen in reactive conditions and therefore is of limited diagnostic value. Aberrant expression of other T-cell antigens may be seen but mainly occurs in the advanced (tumor) stages. Inactivation of p16 *(CDKN2A)* and *PTEN* has been identified in some cases and may be associated with disease progression.

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma (SPTCL) usually presents with subcutaneous nodules, primarily affecting the extremities and trunk. The nodules range in size from 0.5 cm to several centimeters in diameter. In its early stages, the infiltrate may appear deceptively benign, and lesions are often misdiagnosed as panniculitis. However, histologic progression usually occurs, and subsequent biopsies show more pronounced cytologic atypia, permitting the diagnosis of malignant lymphoma.

Atypical lymphoid cells rim individual fat cells. Admixed reactive histiocytes are frequently present, particularly in areas of fat infiltration and destruction. Vascular invasion may be seen in some cases, and necrosis and karyorrhexis are common (see Fig. 72-15, *C*).

The neoplastic cells are CD8-positive T α-β cells, with tumors composed of γ-δ T cells now included under primary cutaneous γ-δ T-cell lymphomas.[39] The cells display an activated cytotoxic immunophenotype (positive for TIA-1, granzyme B, and perforin). These proteins may be responsible for the cellular destruction seen in these tumors.

A hemophagocytic syndrome is less often seen in SPTCL than in panniculitis-like tumors of γ-δ T-cell derivation, but whenever seen, is associated with an adverse prognosis.[40] Patients present with fever, pancytopenia, and hepatosplenomegaly. The cause of the hemophagocytic syndrome appears related to cytokine production by the malignant cells.

Primary Cutaneous γ-δ T-Cell Lymphoma

Primary cutaneous γ-δ T-cell lymphoma is considered a distinct entity, which can involve the subcutis, the dermis, or with epidermal infiltration. These are clinically aggressive tumors. The cells have a cytotoxic phenotype, and similar to normal γ-δ T cells, lack CD5 and express cytotoxic molecules. They may be CD8 positive, or more often, double negative for CD4 and CD8. Although the skin is the most common presenting site, similar lymphomas of γ-δ T-cell origin can present in other extranodal sites, most often the gastrointestinal tract.[41] The cells are invariably EBV negative and show clonal rearrangement of T-cell receptor genes.

Primary Cutaneous CD8-Positive Aggressive Epidermotropic Cytotoxic T-Cell Lymphoma and Primary Cutaneous CD4-Positive Small/Medium T-Cell Lymphoma

These are provisional entities listed in the 2008 WHO classification. *Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma* is an aggressive cutaneous neoplasm that shares many clinical features with primary cutaneous γ-δ T-cell lymphomas but is derived from cytotoxic α-β T cells. As the term implies, the neoplastic cells show prominent epidermotropism.

Primary cutaneous CD4-positive small/medium T-cell lymphoma most often presents with localized skin lesions. It is associated with an excellent prognosis and requires only limited localized therapy unless multiple skin lesions are present. Some authors have questioned whether this lymphoid proliferation should be considered a form of "pseudolymphoma," often containing T-cell clones but

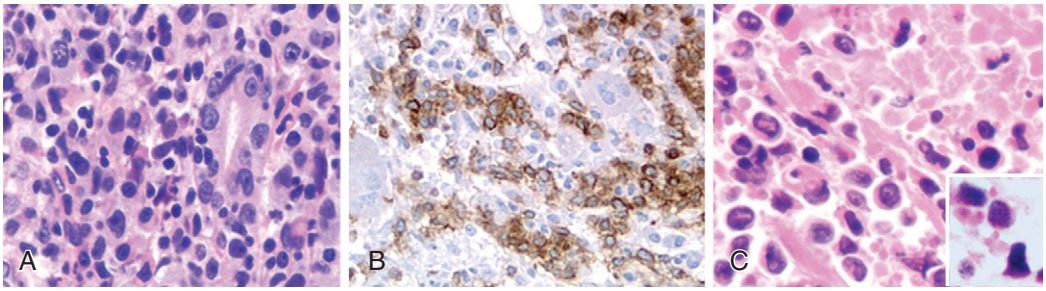

Figure 72-16 T-CELL LYMPHOMA. In enteropathy-associated T-cell lymphoma (EATL) **(A),** there is an abnormal T-lymphoid proliferation with infiltration into the gastrointestinal glandular elements *(center right).* Bone marrow involvement of hepatosplenic gamma δ T-cell lymphoma (HSTCL) is illustrated with a CD2 stain showing the characteristic sinusoidal distribution of the lymphoma **(B).** Extra nodal natural killer cell/T-cell lymphoma typically has marked necrosis **(C).** The malignant cells are Epstein-Barr virus (EBV) positive by in situ hybridization for EBV encoded RNA *(insert).*

having limited potential for progression.[42] The lesions are rich in B cells, and the proliferating T cells have a T_{FH} phenotype.

Enteropathy-Associated T-Cell Lymphoma

Two variants of enteropathy-associated T-cell lymphoma (EATL) are recognized in the WHO 2008, EATL types I and II. EATL type I is associated with either overt or clinically silent gluten-sensitive enteropathy and is largely seen in patients of European extraction; the type II form has a more worldwide distribution. Patients usually present with abdominal symptoms, including pain, small bowel perforation, and associated peritonitis. The clinical course is aggressive, and most patients have multifocal intestinal disease.[43]

In EATL type I, the cytologic composition is somewhat varied; the neoplastic cells show prominent invasion of the mucosa and are cytotoxic T cells most often of α-β origin. The cells also express the homing receptor CD 103 (HML-1) (Fig. 72-16, *A*). Cells with anaplastic features positive for CD30 may be present. In EATL type I, the adjacent small bowel usually shows villous atrophy associated with celiac disease. In EATL type II, the infiltrate is monomorphic composed of medium-sized cells with clear cytoplasm showing prominent epitheliotropism. They are CD56 positive, CD8 positive, and most often of γ-δ T-cell derivation. An association with celiac disease is only seen sporadically, and this form of the disease is relatively common in Asia. Other PTCLs can present with intestinal disease and should be distinguished from EATL. These include the EBV-positive extranodal T-cell/NK cell lymphomas and γ-δ T-cell lymphomas. Both EATL types I and II share some genetic aberrations, including chromosomal gains on 9q33-34.

Hepatosplenic T-Cell Lymphoma

Hepatosplenic T-cell lymphoma (HSTCL) presents with marked hepatosplenomegaly in the absence of lymphadenopathy. The great majority of cases are of γ-δ T-cell origin. Most patients are male, with a peak incidence in young adults. Although patients may respond initially to chemotherapy, relapse has been seen in the vast majority of cases, and the median survival is less than 3 years. Rare long-term survival has been seen after allogeneic hematopoietic cell transplantation.

The cells of HSTCL are usually moderate in size, with a rim of pale cytoplasm. The nuclear chromatin is loosely condensed, with small inconspicuous nucleoli. The pattern of infiltration mimics the homing pattern of γ-δ T cells with marked sinusoidal infiltration in liver and spleen. Abnormal cells are usually present in the sinusoids of the BM but may be difficult to identify without immunohistochemical stains (see Fig. 72-16, *B*). The neoplastic cells also have a phenotype that resembles that of normal resting γ-δ T cells. They are often negative for both CD4 and CD8, although CD8 may be expressed in some cases. CD56 is typically positive. The neoplastic cells express markers associated with cytotoxic T cells, such as TIA-1. However, perforin and granzyme B are usually negative, suggesting that these cells are not activated. Isochromosome 7q is a consistent cytogenetic abnormality and is often seen in association with trisomy 8.

Extranodal Natural Killer Cell/T-Cell Lymphoma, Nasal Type

Extranodal NK cell/T-cell lymphoma, nasal type, is a distinct clinicopathologic entity highly associated with EBV. It is much more common in Asians than in Europeans.[44] Clusters of the disease also have been reported in Central and South America in individuals of Native American heritage, suggesting that ethnic background (i.e., genetic risk factors) may play a role in the pathogenesis of these lymphomas. It affects adults (median age, 50 years), and the most common clinical presentation is a destructive nasal or midline facial lesion. Palatal destruction, orbital swelling, and edema may be prominent. NK cell/T-cell lymphomas have been reported in other extranodal sites, including skin, soft tissue, testis, upper respiratory tract, and gastrointestinal tract. The clinical course is usually aggressive, with a slightly improved median survival in patients with localized disease, in which local radiation therapy may be useful.[44] A hemophagocytic syndrome is a common clinical complication and adversely affects survival.

Extranodal NK cell/T-cell lymphoma, nasal type, is characterized by a broad cytologic spectrum (see Fig. 72-16, *C*). Although the cells express some T cell-associated antigens, most commonly CD2, other T-cell markers, such as surface CD3, are usually absent. The cells express cytoplasmic CD3 but lack T-cell receptor gene rearrangement. In support of an NK cell origin, the cells are usually CD56 positive but do not express CD57 or CD16. EBV is positive in 100% of cases by in situ hybridization.

Aggressive NK cell leukemia is a closely related entity. It presents at a younger age than extranodal NK cell/T-cell lymphoma and is associated with systemic disease and a fulminant clinical course. It has a similar phenotype, EBV association, and epidemiology.

There are other EBV-positive T-cell and NK cell proliferations that are seen mainly in children. These include *systemic EBV-positive T-cell lymphoproliferative disease, hydroa vacciniforme-like lymphoma,* and *mosquito bite allergy,* the latter usually being derived from NK cells. All are seen most often in Asian children but also are reported in Central and South America in individuals of Native American origin. Whereas the latter two conditions affect mainly the skin and have a more indolent clinical course, the systemic disease has a very aggressive clinical course with survival measured in weeks. Systemic

EBV-positive T-cell LPD may arise in a background of chronic active EBV infection.

Hodgkin Lymphomas

Hodgkin lymphoma and NHL have long been regarded as distinct disease entities based on their differences in pathology, phenotype, clinical features, and response to therapy. It is now accepted that the malignant cell of Hodgkin lymphoma is an altered B cell. Therefore, it is not surprising that both biologic and clinical overlaps should occur between these two lymphoma groups, as also shown by GEP in PMBL and cell lines derived from CHL. Although we have become aware of this closer relationship from the histogenetic point of view (hence the name Hodgkin lymphoma), these disorders are still treated with different modalities.

The diagnosis of CHL depends on the identification of Hodgkin/Reed-Sternberg (HRS) cells in an appropriate inflammatory background composed of small T lymphocytes, plasma cells, histiocytes, and granulocytes (often eosinophils).[45] All cases of CHL share certain immunophenotypic and genotypic features. Neoplastic cells are $CD30^{+}$, $CD15^{+/-}$, $CD45^{-}$, and EMA^{-}. Expression of B cell–associated antigens is seen in up to 75% of cases. However, when present, CD20 staining is weaker than that seen in normal B cells with variable in intensity among individual tumor cells. CD79a is usually negative. Ig and T-cell receptor genes are usually germline because of the paucity of tumor cells in the inflammatory background, but using microdissection and polymerase chain reaction amplification for clonal rearrangement of the Ig genes can generally be shown. In addition, the presence of somatic mutations indicates transit through the germinal center.

Sufficient evidence has emerged in recent years to warrant the recognition of nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL) as a distinct entity. Although it resembles other types of Hodgkin lymphoma in having a minority of putative neoplastic cells on a background of benign inflammatory cells, it differs morphologically, immunophenotypically, and clinically from classic Hodgkin lymphoma. The preferred term of Hodgkin lymphoma over Hodgkin disease reflects current knowledge concerning the nature of the neoplastic cell as a lymphocyte.

Nodular Lymphocyte-Predominant Hodgkin Lymphoma

Nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL) usually has a nodular growth pattern (Fig. 72-17) with or without diffuse areas; it is rarely purely diffuse. Nodularity may be more easily recognized using immunohistologic stains with anti–B-cell or antifollicular dendritic cell (FDC) antibodies. Progressively transformed germinal centers are often seen in partially involved lymph nodes or other lymph node sites. The atypical cells have vesicular, polylobated nuclei and small nucleoli. These had been called lymphocytic or histiocytic (L&H) cells, or "popcorn" cells, but the term *LP cell* is now preferred.[17] Although these cells may be very numerous, usually no diagnostic HRS cells are found. The background is predominantly lymphocytes with or without epithelioid histiocyte clusters. Plasma cells are infrequent, and eosinophils and neutrophils are rarely seen. Occasionally, sclerosis may cause lesions to resemble nodular sclerosis.

The atypical cells are $CD45^{+}$-expressing B cell–associated antigens (CD19, 20, 22, 79a), $CDw75^{+}$, $EMA^{+/-}$ $CD15^{-}$, $CD30^{-/+}$, and usually SIg^{-} by routine techniques, although one study reported light-chain restriction. Neoplastic cells positive for IgD are more often found in male patients, median age 21 years.[46] J chain has been demonstrated in many cases. Small lymphocytes in the nodules are predominantly B cells with a mantle zone phenotype. However, numerous T cells are present, with T cells positive for CD57 and PD-1 (CD279) surrounding the LP cells. The proportion of T cells tends to increase over time in sequential biopsies. A prominent meshwork of FDC is present within the nodules. LP cells, when isolated by microdissection, have clonally rearranged Ig genes with evidence of somatic hypermutation.

NLPHL occurs at all ages, in adults more commonly than in children, and in men more than in women. It usually involves peripheral lymph nodes with sparing of the mediastinum. It is usually localized at diagnosis but rarely may be disseminated. Survival is long, with or without treatment, for localized cases. However, when disseminated, the prognosis is often poor. Patients with advanced stage disease may benefit from treatment regimens used for aggressive B-cell lymphomas. Late relapses have been reported to be more common than in other types of Hodgkin lymphoma; it may be associated with or progress to large B-cell lymphoma. Progression to a process resembling T-cell/histiocyte rich large B-cell lymphoma may also been seen.

Classic Hodgkin Lymphoma, Nodular Sclerosis

This variant is most common in adolescents and young adults, but can occur at any age; female cases equal or exceed those in males. The mediastinum is commonly involved; stage and bulk of disease have prognostic importance. Classic Hodgkin lymphoma, nodular sclerosis (NSCHL), is often curable; however, in long-term survivors the risk of secondary malignancies is increased, especially in those receiving both radiation and chemotherapy. NSCHL of the mediastinum

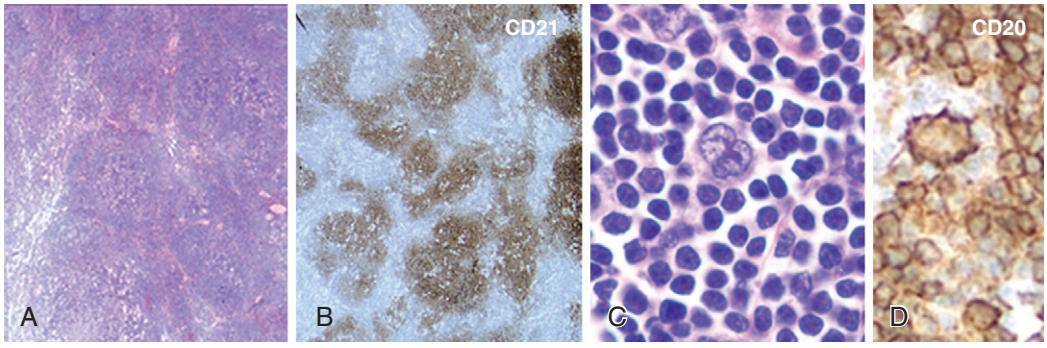

Figure 72-17 NODULAR LYMPHOCYTE PREDOMINANT HODGKIN LYMPHOMA (NLPHLP). Low-power illustration shows vague expansile nodules that efface the lymph node architecture **(A).** The nodules can be accentuated with a stain for germinal center dendritic cells, CD21 **(B).** This indicates that the nodules are germinal center derived. The neoplastic components are the so-called "LP" cells (previously called "L&H" cells or "popcorn" cells) **(C).** Unlike the neoplastic cells of classical Hodgkin lymphoma, these LP cells stain brightly for CD20 **(D)** and are typically $CD45^{+}$, $CD30^{-}$, and $CD15^{-}$.

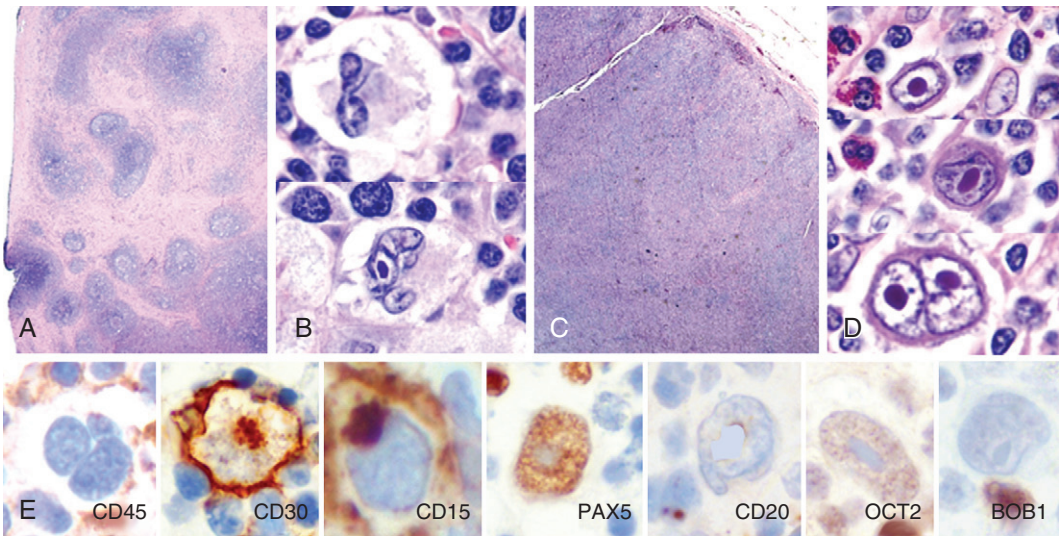

Figure 72-18 CLASSICAL HODGKIN LYMPHOMA, NODULAR SCLEROSING TYPE AND MIXED CELLULARITY TYPE. In nodular sclerosing Hodgkin Lymphoma, broad bands of sclerosis typically divide the lymph node into cellular nodules **(A).** The nodules contain a mixed cellular infiltrate and scattered neoplastic cells with lobular nuclei and retracted cytoplasm **(B).** In mixed cellularity Hodgkin lymphoma, the lymph node is usually diffusely effaced and is without fibrosis **(C).** Classic mononuclear and bi- and multinuclear Hodgkin (H) and Reed-Sternberg (RS) cells are present **(D).** Both the lacunar and HRS cell are typically $CD45^-$, $CD30^+$, $CD15^+$, weak $PAX5^+$, and $CD20^-$. The B-cell transcription factors OCT2 and BOB1 are variable but usually not both or uniformly positive **(E).**

is thought to be closely related to PMBL, and both types of tumors can be seen in the same patient, either as composite malignancy, or sequentially.[47]

The tumor has at least a partially nodular pattern with fibrous bands separating the nodules in most cases (see Fig. 72-18, *A* and *B*). Diffuse areas may be present, as is necrosis. The characteristic cell is the lacunar-type RS cell, which may be very numerous. Diagnostic RS cells are usually also present. The background contains lymphocytes, histiocytes, plasma cells, eosinophils, and neutrophils. It can be graded according to the proportion of the tumor cells and the presence of necrosis (grades I and II). However, grading is considered optional. The immunophenotype and genotype are characteristic of CHL. However, EBV is infrequently positive (<15% of cases).

Classic Hodgkin Lymphoma, Mixed Cellularity

Patients are usually adults; men outnumber women, and the stage is often advanced. The course is moderately aggressive but is often curable. Classic Hodgkin lymphoma, mixed cellularity (CHLMC) has a bimodal age distribution, with a peak in young children and again in older adults. It is often EBV positive, seen in up to 75% of cases. Both CHLMC and the lymphocyte depleted form can be associated with underlying HIV infection. The infiltrate is diffuse without band-forming sclerosis, although fine interstitial fibrosis may be present (Fig. 72-18, *C* and *D*). HRS cells are of the classic type.

Classic Hodgkin Lymphoma, Lymphocyte Depletion

Classic Hodgkin lymphoma, lymphocyte depletion (CHLLD) is the least common variant of CHL and is most common in older people, in HIV-positive individuals, and in non-industrialized countries. It frequently presents with abdominal lymphadenopathy, spleen, liver, and BM involvement without peripheral adenopathy. The stage is usually advanced at diagnosis. It shares many features with CHLMC and appears to represent a continuum with this variant, associated with more frequent neoplastic cells and fewer normal T cells.[45]

The infiltrate is diffuse and often appears hypocellular owing to the presence of diffuse fibrosis and necrosis. Relative to the number of normal lymphocytes, there are large numbers of HRS cells and occasional bizarre "sarcomatous" variants with a paucity of other inflammatory cells. The immunophenotype is characteristic of CHL. Because the histologic differential diagnosis often includes large B- or T-cell lymphoma or ALCL, immunohistochemistry should be performed in most cases. EBV is positive in the majority of cases.

Classic Hodgkin Lymphoma, Lymphocyte Rich

Classic Hodgkin lymphoma, lymphocyte rich (CHLLR) may be nodular or diffuse and contains relatively infrequent HRS cells, which are of the classic type, rather than the LP variants seen in NLPHL. There are infrequent eosinophils or plasma cells. In the nodular form, the HRS cells are seen at the periphery of B cell–rich nodules, mainly in the marginal zone. The neoplastic cells have the immunophenotype of classic HRS cells but morphologically may be difficult to distinguish from LP cells in some cases. Thus, in the past, many cases were misdiagnosed as NLPHL.[48] The genetic features are similar to those of the other variants of CHL. Patients usually present with localized disease and tend to be older than patients with NLPHL.

CHAPTER 73

ORIGIN OF HODGKIN LYMPHOMA

Ralf Küppers

More than 150 years ago, Thomas Hodgkin described several cases of a lymphoproliferative disease, which was later named Hodgkin disease. This malignancy, which is now called Hodgkin lymphoma (HL), has been one of the most enigmatic forms of lymphomas for a long time. This is due to several key features of the disease: First, the pathognomonic and suspected tumor cells of HL, the mononuclear Hodgkin and the bi- or multinucleated large Reed-Sternberg cells, are very rare in the tumor tissue, often accounting for only about 1% of the cells. Thus the molecular analysis of these cells was very much hampered until methods became available to isolate these cells by microdissection from tissue sections. Second, the Hodgkin and Reed-Sternberg (HRS) cells have a very unusual immunophenotype, which does not resemble any normal cell in the hematopoietic system. Therefore immunophenotyping, which was very informative in revealing the cellular derivation of most other lymphoid malignancies, did not help to uncover the cellular origin of HRS cells. Third, only a few cell lines could be established from HL patients, these lines were rather heterogeneous, and for hardly any of these lines was the derivation from the HRS cells in the patient unequivocally shown. Hence it was initially difficult to draw firm conclusions from the study of such lines. Although HL still harbors many secrets, exciting novel insights into the cellular origin of the HRS cells and the pathogenetic processes in their generation have been obtained in the last years, which will be discussed in this chapter.

CLASSIFICATION OF HODGKIN LYMPHOMA

HL is subdivided into classical HL, which accounts for about 95% of cases, and nodular lymphocyte predominant HL (NLPHL). The tumor cells are called *HRS cells* in classical HL and *lymphocyte predominant (LP) cells* in NLPHL (until recently, the tumor cells in NLPHL were called lymphocytic and histiocytic [L&H] cells). Classical HL and NLPHL differ in the histologic picture, the morphology and immunophenotype of the tumor cells, and multiple clinical features. Classical HL is further subdivided into four subforms: nodular sclerosis, mixed cellularity, lymphocyte-rich classical, and lymphocyte depletion HL. Again, differences in the histologic picture and HRS cell morphology are the basis for this subtyping (see Chapter 72 for a detailed description).

B-cell Development and Differentiation

Because we now know that HRS and LP cells are derived from B cells (see later), a brief outline of B-cell development and differentiation is given first. B cells are generated in the bone marrow from hematopoietic stem cells in a multistep developmental process. The key determinant for B-cell development is the generation of a functional B-cell receptor (BCR), which is composed of two identical immunoglobulin (Ig) heavy chains and two identical light chains, the latter of which can be of the κ or λ type. B-cell development is initiated when common lymphoid progenitors undergo gene rearrangements at the Ig gene heavy chain locus. The variable part of the antibody heavy chain is composed of three gene segments: variable (V), diversity (D) and joining (J). First, a randomly selected D_H gene segment is rearranged to one J_H gene segment. In the next step, a V_H gene segment is rearranged to a D_H-J_H joint. If the rearrangement is in-frame and productive, a heavy chain can be expressed and the developmental stage of a pre-B cell is reached. In the next step, $V_κ$ to $J_κ$ rearrangements occur to generate a κ light chain. If this is not successful, V gene rearrangement processes take place at the λ light chain locus. B cells expressing a functional (and nonautoreactive) BCR are released into the periphery and express their BCR as IgM and IgD receptors—that is, two different classes of the heavy chain constant region. The first D_H-J_H rearrangements are not completely specific for B-lineage cells, but $V_HD_HJ_H$ rearrangements and light chain gene rearrangements are highly specific for B cells. Thus their detection in a cell unequivocally defines that cell as a B cell. Moreover, because of the availability of multiple V, D, and J gene segments and additional diversity generated at the joining sites of the rearranging gene segments, a V(D)J rearrangement (in particular for the heavy chain locus) is unique for each B cell and thus can be used as a clonal marker for B cells deriving from the same mature B cell.

If B cells are activated through binding of antigen to their BCR and through cognate help from T-helper cells, the cells undergo a T-dependent immune response in specific histologic structures, the germinal centers (GC), in lymph nodes or other secondary lymphoid organs. In these follicles, activated B cells undergo massive clonal expansion and further diversify their BCR through two processes: somatic hypermutation and class switching. The process of somatic hypermutation introduces point mutations and some deletions and duplications at a very high rate into the Ig heavy and light chain V region genes. This randomly modifies amino acids in the V regions, and in a selection process involving follicular dendritic cells and follicular T-helper cells, B cells expressing mutated BCR with increased affinity to the stimulating antigen are positively selected, whereas B cells acquiring unfavorable mutations undergo apoptosis within the GC microenvironment (Fig. 73-1). Unfavorable mutations include clearly destructive mutations, such as nonsense mutations and deletions or duplications causing reading frame–shifts that prevent expression of a BCR as such. Other disadvantageous replacement mutations still allow BCR expression but reduce the affinity to the antigen. After multiple rounds of proliferation, mutation, and selection, positively selected B cells expressing a high-affinity BCR differentiate into long-lived memory B cells or plasma cells and exit the GC. Many GC B cells also undergo class switching before they are selected into the memory or plasma cell pool. In class switching, the originally expressed Cμ and Cδ heavy chain constant region genes (encoding IgM and IgD, respectively) are replaced by downstream-located Cγ, Cα, or Cε genes, encoding IgG, IgA, and IgE heavy chains, respectively, so that antibodies with altered effector functions are generated. At all stages of their development, B lineage cells are selected for expression of the appropriate BCR, and cells failing this selection are eliminated.

Cellular Origin of Lymphocyte Predominant Cells in Nodular Lymphocyte Predominant Hodgkin Lymphoma

LP cells in NLPHL express multiple typical B cell markers, such as the surface molecules CD20 and CD79 and the transcription factors PAX5, OCT-2, and BOB1 (Table 73-1).[1] LP cells mostly lack

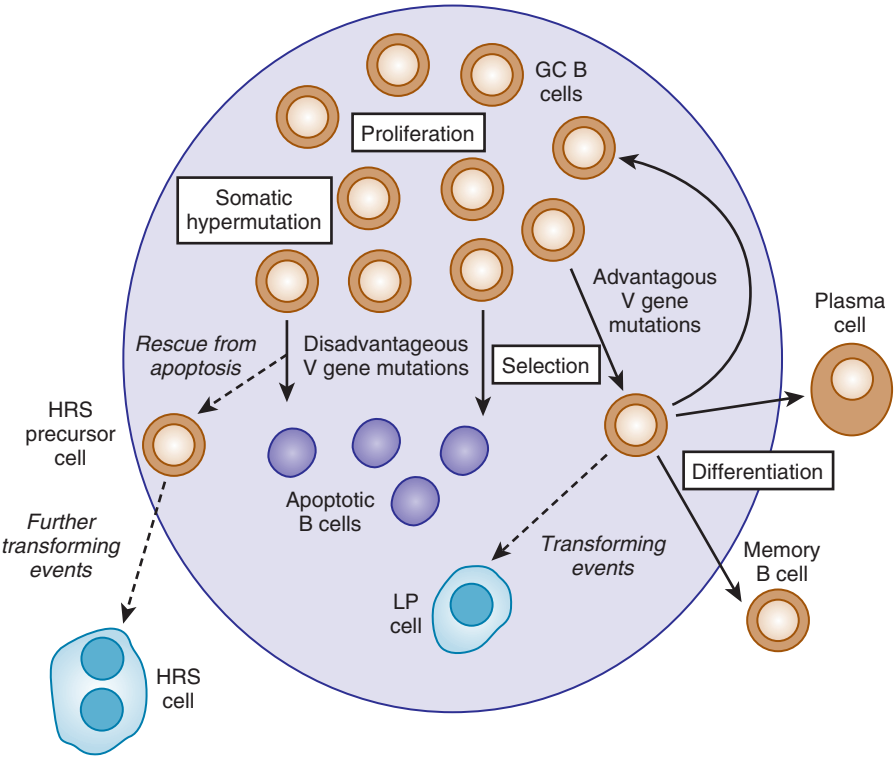

Figure 73-1 THE GERMINAL CENTER REACTION AND A SCENARIO FOR HODGKIN AND REED-STERNBERG AND LYMPHOCYTE PREDOMINANT CELL DERIVATION. Antigen-activated B cells that receive costimulatory signals from T-helper cells establish germinal center (GC) reactions in T-dependent humoral immune responses. In the GC, the activated B cells undergo massive clonal expansion in the dark zone. The proliferating GC B cells are called *centroblasts*. In the centroblasts, the process of somatic hypermutation is activated, which introduces somatic mutations at a very high rate into rearranged Ig V genes. Centroblasts migrate into the light zone and become resting centrocytes. Centrocytes are then selected based on their BCR. Most Ig V gene mutations will be disadvantageous (e.g., when they cause premature stop codons or lead to aminoacid changes that reduce the affinity of the BCR to the immunizing antigen) and will cause apoptotic death of the respective B cells. GC B cells acquiring affinity-increasing mutations will be positively selected by interaction with T-helper cells and follicular dendritic cells (not shown). Positively selected centrocytes may either return to the dark zone for further rounds of proliferation, mutation, and selection, or they differentiate into memory B cells or plasma cells and exit the GC. LP cells of NLPHL express functional Ig V genes and proliferate in a follicular microenvironment resembling GC. Thus these cells are likely derived from selected GC B cells. HRS cells in classical HL often carry destructive Ig V gene mutations, indicating that they derive from GC B cells that normally would have undergone apoptosis (i.e., pre-apoptotic GC B cells). Initial transforming events in HRS cell pathogenesis might have occurred already at a pre–GC B cell differentiation stage, or they might happen in the GC. In EBV-positive cases, EBV is a good candidate for a factor that allows GC B cells with destructive Ig V gene mutations to escape from apoptosis.

expression of markers of other hematopoietic cell lineages. Thus their immunophenotype suggests a B-cell origin. Moreover, LP cells are located in follicular structures in close association with follicular dendritic cells and GC-type T-helper cells, suggesting a close relationship with GC B cells. Indeed, LP cells express the transcription factor BCL6, the main regulator of the GC B cell differentiation program. They also express activation-induced cytidine deaminase (AID), an enzyme that regulates somatic hypermutation and class switching in GC B cells. Thus all of these phenotypic features point to a GC B cell origin of LP cells (see Table 73-1). This was further corroborated at the genetic level when clonally rearranged and productive Ig V region genes were amplified from isolated LP cells. These rearrangements were always somatically mutated. In some cases, intraclonal diversity of V region genes was observed, indicating ongoing somatic hypermutation during clonal expansion. Therefore the Ig V gene analysis further strongly supported a GC B cell origin of LP cells (Fig. 73-1). The detection of the same V gene rearrangements in all LP cells of a given NLPHL case was also important, because this firmly established for the first time the monoclonality of the LP cells, a hallmark for tumor cells. A recent gene expression profiling study of primary LP cells indicated that LP cells have partly downregulated a fraction of typical B cell genes and that their gene expression pattern indicates a relationship to late GC B cells on the way to becoming post-GC memory B cells.[2]

Cellular Origin of Hodgkin and Reed-Sternberg Cells in Classical Hodgkin Lymphoma

As mentioned earlier, HRS cells show a very peculiar immunophenotype that does not resemble any normal hematopoietic cell type. HRS cells express markers of different cell lineages in a fraction or even most cases, including B cell genes (e.g., PAX5, IRF4), T cell genes (e.g. Notch-1, GATA3), natural killer cell genes (ID2), myeloid genes (e.g., CD15, CSF1R), and dendritic cell markers (e.g., CCL13, fascin, restin) (Table 73-1).[2-4] Therefore immunohistochemical studies could not resolve the cellular origin of HRS cells. In addition, the first cell lines established from HL patients and presumed to be

Table 73-1 Comparison of Phenotypic and Genetic Features of Hodgkin and Reed-Sternberg Cells of Classical Hodgkin Lymphoma and Lymphocyte Predominant Cells of Nodular Lymphocyte Predominant Hodgkin Lymphoma

Feature	Hodgkin and Reed-Sternberg cells	Lymphocyte Predominant cells
Somatically mutated Ig V genes	Yes (very rare exceptions)	Yes
Crippling Ig V gene mutations	Yes (>25% of cases)	No
Ongoing somatic hypermutation	No	Yes (moderately)
Presumed cellular origin	Pre-apoptotic GC B cells	Positively selected, mutating GC B cells
Rare cases with a T-cell origin	Yes (<5%)	No
B-cell receptor expression	No	Yes
Expression of B-cell transcription factors (e.g., OCT2, BOB.1, PU.1, PAX5, E2A)	Rarely and/or at low levels	Yes
Expression of B-cell surface antigens (e.g., CD19, CD20)	No or rarely	Yes
Expression of GC B cell markers (e.g., BCL6, AID, HGAL, GCET)	No or rarely	Yes
Expression of molecules involved in antigen presentation and interaction with T-helper cells (e.g., CD40, CD80, CD86, MHC class II)	Yes	Yes
Expression of markers of non-B cells (e.g., CCL13, Notch1, GATA3, ID2, CSFR1)	Yes	No
EBV infection of tumor cells	Yes (30%-40%)	No

derived from HRS cells were either of B-cell origin, of T-cell origin, or of nonlymphoid origin (discussed in further detail later). The origin of HRS cells was finally clarified when HRS cells microdissected from tissue sections were analyzed for rearranged Ig V region genes. These studies revealed that HRS cells in nearly all cases carry clonal Ig heavy and light chain gene rearrangements.[5] This established their B-cell nature, because such rearrangements are highly specific for B cells. Moreover, with rare exceptions, the rearranged V region genes were highly mutated, pointing to a derivation from GC or post-GC B cells.[5] Intraclonal V gene diversity was not observed, showing that the process of somatic hypermutation is no longer active in these cells. There is also indication that many HRS cell clones underwent class-switch recombination, a further antigen-driven and B cell–specific process. Thus these genetic features of the rearranged Ig genes unequivocally demonstrate that the HRS cells are derived from mature B cells that had been activated by antigen. Although some initial studies reported polyclonality of HRS cells, these results could not be verified, and additional analyses firmly established the monoclonality of the HRS cells in a given case.

Surprisingly, in about a quarter of the cases of classical HL, the Ig V gene rearrangements carried clearly destructive mutations that rendered originally functional V region genes nonfunctional.[5] Such "crippling" mutations included deletions and insertions causing loss of the correct reading frame, as well as nonsense mutations. As discussed earlier, destructive mutations regularly happen in mutating GC B cells, but this normally results very efficiently in the removal of the cells by apoptosis. Thus it is highly likely that the GC B cells that acquired the destructive mutations already carried some transforming events that allowed them to escape apoptosis (Fig. 73-1). Of note, most disadvantageous mutations that cause apoptosis of normal GC B cells are likely replacement mutations that reduce affinity to the antigen or that interfere with the proper folding and/or pairing of the Ig heavy and light chains. These mutations cannot be easily recognized by looking at the V gene sequences. Thus the clearly crippling mutations likely represent only the "tip of the iceberg," and we have speculated that HRS cells, as a rule, derive from the pool of pre-apoptotic GC B cells (Fig. 73-1).[5] Rare cases of classical HL with unmutated V region genes have also been described. In such cases, the HRS cells may stem from pre-GC B cells. However, because GC B cells acquire their apoptosis proneness upon entering the GC even before starting to undergo hypermutation, it is also conceivable that such cases may originate from GC founder cells.

Decisive steps in HL pathogenesis, therefore, become effective or take place in GC B cells. Thus although some final transforming events may well occur when HRS precursor cells have already left the GC microenvironment, for the reasons discussed earlier, classical HL is considered as a GC B cell–derived malignancy.

T Cell–Derived Classical Hodgkin Lymphoma

The observation that in a fraction of cases the HRS cells express several T cell markers (e.g., CD3, granzyme B, perforin, T cell intracellular antigen 1) prompted studies aimed to clarify whether in such cases the HRS cells might derive from T cells. Analysis of HRS cells from several cases with T cell marker expression showed that most of these cases nevertheless are B cell–derived. However, several cases were identified that lacked Ig V gene rearrangements and that showed clonal T-cell receptor gene rearrangements.[6,7] Thus these cases have a T cell origin. Because the cellular origin of a lymphoma clone is a key factor for current lymphoma classification, it is a matter of debate whether lymphomas with HRS cells of T cell origin should be called *HL* or whether they should be considered a rare, separate type of T-cell lymphoma. However, because these cases are very rare (likely accounting for less than 5% of classical HL), because it is so far not possible to identify them by immunohistochemistry, and because it is unclear whether such cases differ in their clinical behavior from B cell–derived classical HL, there is currently no easy way to resolve this issue. Notably, in gene expression studies of HL cell lines, HDLM2 (a T cell–derived HL cell line) clustered more closely to B cell–derived HL cell lines than to other T-cell lymphoma lines, suggesting that B cell– and T cell–derived HRS cells have a similar gene expression pattern.

Hodgkin Lymphoma Cell Lines

Tumor cell lines are very valuable tools for detailed genetic, biochemical, and functional studies of a malignancy. Thus there have been many attempts to establish such lines from HL patients. However, this has proved to be a very difficult task, and less than 10 HL cell lines exist. A main reason for the difficulty in growing HRS or LP cells in culture is most likely their dependence on survival signals from the cellular microenvironment in the disease-affected lymph nodes. Of note, all of the existing HL lines are derived from end-stage patients and were not established from lymph nodes, but rather from peripheral blood, bone marrow, or pleural effusions. This suggests that only when the HRS cells have become independent from the lymph node microenvironment in the patient do they also have a chance to survive in suspension culture. The existing HL lines are

Table 73-2 Characteristics of Hodgkin Lymphoma Cell Lines*

Cell Line	Hodgkin Lymphoma Subtype	Cellular Origin	Known Genetic Lesions in Oncogenes or Tumor Suppressor Genes	Remarks
L428	Classical	B cell	NFKBIA, NFKBIE, SOCS1, TP53	
L540	Classical	T cell		
L591	Classical	B cell		Only EBV-positive line
L1236	Classical	B cell	TNFAIP3, CD95, SOCS1, TP53	Only line with proven origin from HRS cells in patient
KMH2	Classical	B cell	NFKBIA, TNFAIP3, CYLD	
HDLM2	Classical	T cell	TNFAIP3, SOCS1, TP53	
UHO-1	Classical	B cell	TNFAIP3, TRAF3	
SUP-HD1	Classical	B cell		
DEV	NLPHL	B cell	BCL6 (translocation)	

*A few additional lines have been published (HO, ZO, HD-70, HKB-1), but these have not been used in published studies in recent years, so it is unclear to the author whether they still exist, and very little is known about their phenotypic, functional, and genetic features.

L428, L540, L591, L1236, KMH2, HDLM2, UHO-1, SUP-HD1 and DEV (Table 73-2). Most lines are of B-cell origin, but HDLM2 and L540 are T cell–derived. L591 is the only HL line that is Epstein-Barr virus (EBV)–positive. Among primary cases of classical HL, about 30% to 40% show an infection of the HRS cells by EBV (see further details later). Notably, L591 cells do not have the typical EBV gene expression pattern of primary EBV-infected HRS cells, which should be kept in mind when using this line for gene expression or functional studies. The DEV line was originally reported as being derived from a case of classical HL, but subsequent more-detailed phenotypic and gene expression studies indicated that this is indeed the only existing cell line from a patient with NLPHL. Although the phenotype and genotype of these lines fits well with their presumed origin from HRS cells (or LP cells in the case of DEV), L1236 is the only cell line for which the derivation from the HRS cell clone of the patient from which it was established was unequivocally proven. In 1998 a line from a pediatric HL patient was established (HKB-1), but no further studies with this line were reported. Originally, the CO line was also published as an HL cell line. However, later studies showed that this line represents a cell culture contamination. Also the HD-Myz line was for a long time considered to be a classical HL cell line. However, it was later discovered that the phenotype of the line differs in key aspects from the phenotype of the primary HRS cells of the respective patient. Even more important, HD-Myz lacks Ig- and T-cell receptor gene rearrangements and is presumably of myeloid origin. Considering the fact that all informative HL cases that have been studied in detail for a lymphoid origin have turned out to be B cell–derived, or in rare cases T cell–derived, the nonlymphoid origin of HD-Myz argues against its derivation from HRS cells; thus this line should no longer be used as a model for HL.

Relationship Between Hodgkin Cells and Reed-Sternberg Cells

The population of HRS cells is always composed of a mixture of mononuclear Hodgkin cells and bi- or multinucleated Reed-Sternberg cells. It is thus an intriguing question how these two types of cells are related to each other. It was proposed that cell fusion might be involved in the generation of Reed-Sternberg cells from Hodgkin cells. However, in HL cell line models, fusions of Hodgkin cells resulting in the generation of Reed-Sternberg cells were rendered unlikely. Indeed, there is now firm evidence from studies of HL cell lines that Reed-Sternberg cells develop from mononuclear Hodgkin cells through a process of endomitosis, that is, nuclear division without cellular division. It was also discussed whether the whole HRS cell clone could derive from a cell fusion (e.g., a fusion of a B cell with a non-B cell). Such a scenario was attractive because it might have provided an explanation for the mixed immunophenotype and the usually aneuploid karyotype of the HRS cells. However, generation of the HRS cell clone through fusion was excluded by molecular studies.

Potential Hodgkin and Reed-Sternberg Precursor or Stem Cells

Another interesting question is whether the rare $CD30^+$ HRS cells represent the whole tumor cell clone in the HL tissue or whether further tumor clone members are present among the smaller, $CD30^-$ cells in the microenvironment. A fluorescence in situ hybridization study combined with CD30 immunostaining for cells with numeric chromosomal aberrations argued in favor of the existence of tumor cells among CD30-negative cells.[8] However, only two cases were studied, and numeric chromosomal aberrations (i.e., trisomies) are not stringent clonal markers. In a single-cell Ig V gene analysis of EBV-positive HRS cells and EBV-infected CD30-negative cells, it was found that the HRS cells and the small $CD30^-$ EBV-infected B cells carried distinct V gene rearrangements in nearly all instances.[9] Because EBV infection of HRS cells is a clonal event, so that in EBV^+ HL cases all members of the tumor clone should carry the virus, this finding was taken as an argument that the HRS cell clone does not have additional members among CD30-negative lymphocytes.

In several types of tumors, cancer stem cells were identified. These cells are defined as rare cells that have a particular proliferative potential and that sustain the tumor clone, whereas the bulk of the tumor clone lacks the potential to regrow to a full tumor. One study described the existence of HRS precursor cells in HL that fulfill at least some key features of cancer stem cells. In that work, it was reported that $CD20^+BCR^+CD30^-$ cells belonging to the HRS cell clone exist in the peripheral blood of HL patients and that these cells express the stem cell marker aldehyde dehydrogenase.[10] However, this finding was criticized because the markers for a clonal relationship between the HRS and non-HRS cells were unreliable and even argued, in part, against a relationship of the cells.[11] Moreover, a previous highly sensitive study that searched for HRS clone members in the peripheral blood failed to identify such cells.[12] Thus there is currently no convincing evidence for the existence of $CD20^+BCR^+$ HRS stem cells. In any case, it needs to be considered that HRS cells carry clonal and somatically mutated Ig V gene rearrangements; thus if HRS stem cells exist, they must be mature GC-derived B cells that carry the same Ig gene rearrangements and mutation pattern as the HRS cells.

The issue of potential subpopulations among the HRS cell clone with specific features in terms of proliferative potential and chemotherapy resistance was also addressed by searching for *side population*

cells, which are defined as cells that extrude the Hoechst dye 33342, usually because they express drug transporters of the ABC family, such as the multidrug resistance 1 gene. In several types of tumors, side population cells were shown to share features with cancer stem cells (e.g., increased proliferative potential and chemotherapy resistance). Side population cells were indeed detected at low frequency (about 0.5% of cells) in some HL cell lines, and these cells showed increased resistance to chemotherapeutic drugs.[13,14] The side population cells had the phenotype of small Hodgkin cells and they were positive for CD30 and negative for CD19 and CD20. Hence these cells are different from the cells identified earlier as potential HRS stem cells. Notably, side population cells were able to reestablish the full HRS cell clone upon subcloning. However, not all HL cell lines showed side population cells, arguing against a general role of these cells in the maintenance of the HRS cell clone. Moreover, although side population cells were also identified in cell suspensions of HL lymph nodes, it remains to be clarified whether these cells belong to the HRS cell clone. Thus, there are exciting developments regarding the potential existence of subpopulations among the HRS cell clones with specific biologic features, but additional studies are needed to characterize these cells and reveal their relevance for the HRS clone in vivo.

Lessons From Composite Lymphomas

Composite lymphomas are very rare lymphomas in which an HL and a non-Hodgkin lymphoma (NHL) occur in the same patient. In a strict definition of composite lymphoma, this happens concurrently, but there are also cases where an HL may occur either before or after an NHL in the same patient. There are a few cases where the two lymphomas are not related to each other and hence represent the chance occurrence of two unrelated malignancies developing in parallel in a patient. However, in most composite lymphomas that have been molecularly studied for their clonal relationship, it was found that the lymphomas share a common origin.[15,16] The detailed study of the rearranged Ig V genes of such cases revealed that although, in many cases, the clonally related V region genes of the lymphomas share a number of somatic mutations, there are often additional mutations that were present only in the HRS cells and others only in the NHL B cells.[15,16] This showed that the two lymphomas have a common precursor, most likely a mutating GC B cell, and that the two lymphomas most likely developed from two distinct members of the GC B cell clone (Fig. 73-2). Thus these composite lymphomas usually do not represent the transformation of one lymphoma into the other but, rather, the parallel development of the two malignant clones from a common, premalignant precursor cell. It is likely that some transforming events were already present in the common precursor, but distinct daughter cells of this GC B cell later acquired different mutations, leading to the generation of the two distinct B-cell malignancies (Fig. 73-2). Therefore composite lymphomas are intriguing models to study the multistep transformation process in lymphomagenesis. In an initial study of several composite lymphomas for shared and distinct transforming events, examples for such genetic lesions were indeed identified.[17]

A further important aspect of the molecular studies of composite lymphomas is that they provide further evidence for the derivation of HRS cells in classical HL from GC B cells, because the clonal relationship with shared and distinct somatic Ig V gene mutations of an HRS cell clone and a typical GC B cell–derived lymphoma (e.g., follicular lymphoma or diffuse large B-cell lymphoma) strongly supports a common GC B-cell origin of both malignancies.

The Role of Epstein-Barr Virus in Classical Hodgkin Lymphoma

In about 40% of cases of classical HL in the Western world, and in about 90% of childhood HL cases in Central and Southern America, HRS cells are infected by EBV. Molecular analyses of EBV$^+$ cases showed that EBV infection of HRS cells is a clonal event (i.e., EBV

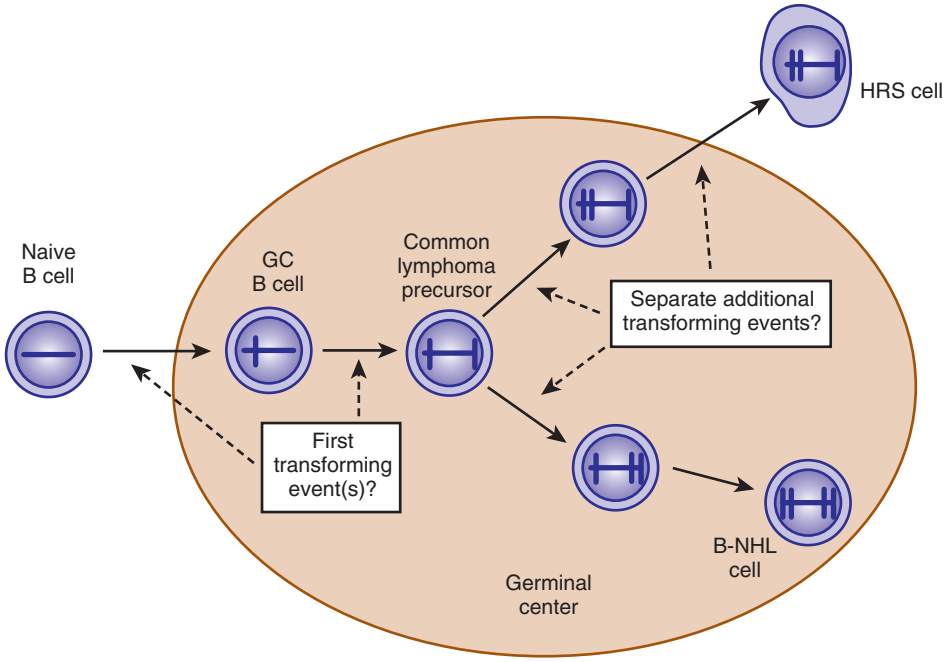

Figure 73-2 SCENARIO FOR THE GENERATION OF COMPOSITE LYMPHOMAS. Composite lymphomas are very rare combinations of a classical HL and an NHL. Detailed molecular analysis of rearranged Ig V genes in several such cases revealed that, in most instances, the two lymphomas are clonally related. Notably, the pattern of both shared and distinct V gene mutations in the majority of these cases revealed that the two lymphomas share a common precursor, but developed separately from this precursor. The direct clonal relationship of HRS cells with typical GC B cell–derived NHL is a further strong argument for a GC derivation of HRS cells. The horizontal line within the cells indicates an Ig V region gene; the vertical lines indicate somatic Ig V gene mutations. *(Modified from Bräuninger A, Hansmann ML, Strickler JG, et al.: Identification of common germinal center B-cell precursors in two patients with both Hodgkin's disease and non-Hodgkin's lymphoma,* New Engl J Med *340:1239, 1999.)*

infected or was already present in the founder cell of the HRS cell clone. EBV-positive HRS cells typically show a latency II gene expression pattern, which is characterized by expression of the EBV nuclear antigen 1 (EBNA1) and the two latent membrane proteins 1 and 2a (LMP1 and LMP2a, respectively). EBNA1 is essential for the replication of the EBV episome in proliferating cells. LMP1 is an oncogene, and one of its main functions is to cause constitutive NF-κB activation by mimicking an activated CD40 receptor. LMP2a has a cytoplasmic motif that resembles the signaling motif of the BCR. LMP2a can, on the one hand, diminish BCR signaling by recruiting BCR signaling components away from the BCR, but on the other hand, it mimics a tonic BCR signal. Strikingly, all HRS cell clones with clearly destructive Ig V gene mutations that prevent the expression of a BCR at all were found to be EBV-positive.[18] Hence it appears that in GC B cell precursors of HRS cells that acquired BCR-destructive mutations, EBV is essential to rescue these cells from apoptosis upon loss of BCR expression. This scenario is supported by studies showing that EBV can rescue BCR-deficient GC B cells from apoptosis, and that LMP2a has an important role in this process.[19] Whether the BCR-mimicking function is still important in the established HRS cell clone is unclear. The downregulation of most components of BCR signaling in HRS cells indicates that LMP2a does not have this role in the established HRS cell clone.

Genetic Lesions in Hodgkin and Reed-Sternberg and Lymphocyte Predominant Cells

The molecular analysis of HRS and LP cells for genetic lesions is hampered by the rarity of these cells. Nevertheless, we are now aware of a number of transforming events, especially for HRS cells. The recognition of constitutive activity of the NF-κB transcription factor, which is normally only transiently activated in lymphocytes, prompted studies of whether gene mutations might cause this deregulated activity. Inactivating mutations in the gene NFKBIA, which encodes the main inhibitor of NF-κB (i.e., IκBα) were detected in 10% to 20% of cases of classical HL (Fig. 73-3).[1] Also mutations in the NFKBIE gene were found. Genomic gains of the REL gene, encoding one of

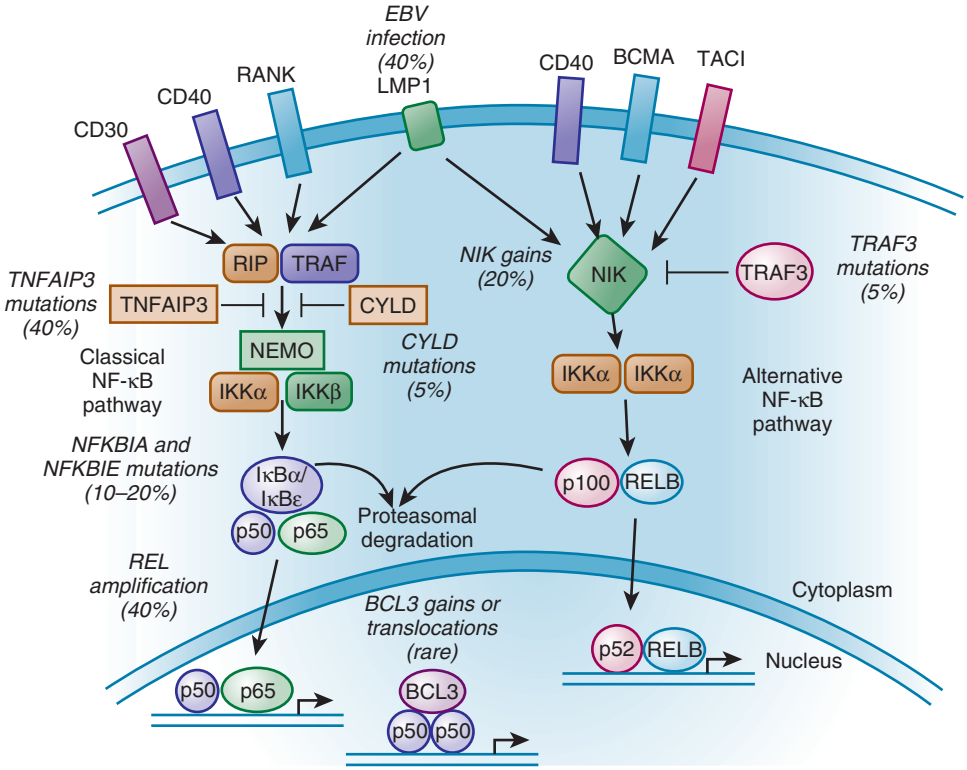

Figure 73-3 MECHANISM OF NF-κB ACTIVATION IN HODGKIN AND REED-STERNBERG CELLS. A classical and an alternative NF-κB signaling pathway are distinguished. In the classical NF-κB pathway, stimulation of numerous receptors (e.g., RANK, CD30, and CD40) leads via TNF receptor–associated factors (TRAFs) and other associated factors, such as the receptor-interacting protein (RIP), to activation of the IKK complex. The IKK complex is composed of IKKα, IKKβ, and NEMO. The activated IKK complex phosphorylates the NF-κB inhibitors IκBα and IκBε, which are encoded by the NFKBIA and NFKBIE genes, respectively. The phosphorylation marks the IκB factors for ubiquitinylation and subsequent proteasomal degradation. Thus the NF-κB transcription factors (e.g., p50/p65 or p50/REL heterodimers) are no longer retained in the cytoplasm and translocate into the nucleus, where they activate multiple genes. The signal transduction from TRAFs/RIP to the IKK complex can be inhibited by A20/TNFAIP3, which removes activating ubiquitins from RIP and TRAFs and additionally links ubiquitins to these molecules to mark them for proteasomal degradation. In the alternative NF-κB pathway, activation of receptors such as BCMA, CD40, and TACI causes stimulation of the kinase NIK, which then activates an IKKα complex. Activated IKKα processes p100 precursors to p52 molecules, which translocate as active p52/RELB NF-κB heterodimers into the nucleus. HRS cells show constitutive activity of the classical and alternative NF-κB signaling pathways. This activity is mediated by diverse mechanisms, including receptor signaling through CD40, RANK, BCMA, and TACI; genomic REL and NIK amplifications; destructive mutations in the TNFAIP3, NFKBIA, and NFKBIE genes; and signaling through the EBV-encoded latent membrane protein 1. HRS cells may also harbor nuclear BCL3/$(p50)_2$ complexes, and in a few cases the strong BCL3 expression appears to be mediated by genomic gains or chromosomal translocations of this gene. In rare instances, inactivating mutations in the inhibitory factors TRAF3 and CYLD have been found. *(Modified and updated from Küppers R: The biology of Hodgkin's lymphoma,* Nature Rev Cancer *9:15, 2009.)*

the NF-κB factors, are present in about 40% of classical HL. More recently, inactivating mutations in TNFAIP3, a further negative regulator of NF-κB, were detected in 40% of HRS cell clones.[20,21] Of interest, most cases with TNFAIP3 mutations were EBV-negative, suggesting that EBV infection and TNFAIP3 mutations are alternative mechanisms in HL pathogenesis. Reestablishing wild-type TNFAIP3 in HL cell lines reduced NF-κB activity and survival, establishing that TNFAIP3 functions as a tumor suppressor gene in this lymphoma.[21] For CYLD, another tumor suppressor gene and negative regulator of NF-κB, inactivating mutations were found in one HL cell line, but not in several primary cases of HL studied, indicating that mutations in this gene also occur in HRS cells, albeit at a low frequency. Rare mutations were recently also found in TRAF3, a negative regulator of the noncanonical NF-κB pathway. Finally, the NIK kinase gene, encoding a major activating factor for the noncanonical NF-κB pathway, shows gains in 20% of classical HL.[22]

Although LP cells of NLPHL also show constitutive NF-κB activity,[2] no destructive mutations were found in TNFAIP3 and NFKBIA in these cells.[23] Because there are also no indications for REL gains in LP cells, and because these cells are not infected by EBV, the mechanisms causing NF-κB activation in HRS and LP cells are strikingly different.

A second signaling pathway that shows constitutive activity in HRS cells and for which mutations have been found in various pathway members is the JAK/STAT pathway. This is the main pathway for cytokine signaling. Upon activation of cytokine receptors, JAK kinases bind to the receptors and become activated. The activated JAKs then phosphorylate and thereby activate STAT factors, which upon phosphorylation and dimerization translocate into the nucleus and function as transcription factors. Frequent genomic gains of JAK2 and also rare translocations involving this gene have been detected in HRS cells. However, activating point mutations in the JAK2 gene, although they are frequent in other types of hematologic diseases, are absent in HRS cells. SOCS1, a main inhibitor of this signaling pathway, is inactivated by somatic mutations in the HRS cells in about 40% of cases of classical HL.[24] SOCS1 mutations were also found in LP cells.[25]

Notably, the genomic region on 9p24, which harbors the JAK2 gene and which shows gains in HRS cells, also encompasses the gene JMJD2C, which encodes a histone demethylase, and the programmed death 1 (PD-1) ligand genes PD-L1 and PD-L2.[26,27] PD-1 ligands can inhibit PD-1–expressing T cells and thereby may contribute to the immunosuppressive microenvironment in HL.[26] A functional role of JMJD2C in HRS cells is indicated from the finding that downregulation of its expression in HL cell lines is toxic for these cells.[27]

Because disturbed apoptosis seems to be a key aspect of classical HL pathogenesis, numerous regulators of apoptosis were also studied in HL cell lines and/or primary HRS cells. Mutations in the TP53 gene were found in three HL cell lines and a few primary cases.[28] Mutations in the CD95 gene were found in less than 10% of cases, and no mutations were found in the CD95 signaling components CASP8, CASP10, and FADD.[28] Moreover, no mutations were detected in the proapoptotic gene BAD; mutations in ATM are also very rare.[28]

Chromosomal translocations, usually involving one of the Ig loci and an oncogene, are a hallmark of most B cell lymphomas. Also in classical HL, chromosomal breaks involving the Ig loci were detected by fluorescence in situ hybridization in about 20% of cases. However, the translocation partners are in most cases unknown. In a few instances, BCL2, BCL3, BCL6, or MYC were identified as partners of the translocations. This also includes composite lymphomas in which the clonally related classical HL and the B cell NHL were found to carry the identical translocation—for example, a BCL2-IgH translocation in a composite classical HL/follicular lymphoma.[17] Notably, Ig locus–associated translocations usually function by causing deregulated expression of the translocated oncogene that has been brought under the control of the Ig regulatory elements, which are active in normal B cells and B cell NHL. Because the Ig loci are largely silenced in HRS cells, it is still unclear whether the partner genes of Ig locus–associated translocations in HRS cells are still active and pathogenetically relevant. Perhaps the translocations were important during early stages of HRS cell pathogenesis, when the lymphoma precursor cells still had a B-cell gene expression program, but became less important during later stages of the multistep transformation process. Alternatively, it should also be considered that translocations might function by mechanisms other than Ig enhancer–driven oncogene overexpression (e.g., promoter replacement or tumor suppressor gene inactivation).

Recently, recurrent translocations involving the MHC class II transactivator gene CIITA were found in about 15% of classical HL.[29] These translocations involved heterogeneous partner genes and seemed to function by impairing CIITA function and hence dampening MHC class II expression.

For LP cells of NLPHL, few genetic lesions are known. Besides the SOCS1 mutations mentioned earlier, translocations involving the BCL6 gene are frequently found.[30] BCL6 encodes a transcription factor that orchestrates the GC B-cell differentiation program and that has an oncogenic function when constitutively expressed in B cells.

FUTURE DIRECTIONS

It is now firmly established that HRS and LP cells stem from mature B cells. A few cases with features of classical HL and a T-cell origin of the HRS cells exist. HRS cells in classical HL appear to derive from crippled GC B cells, whereas LP cells likely originate from antigen-selected GC B cells. HRS cells show deregulated activation of multiple signaling pathways, and for the NF-κB and JAK/STAT pathway, numerous genetic lesions have been identified that contribute to the deregulated activation of these pathways. HRS cells show a nearly complete loss of the B-cell gene expression program.[4] As normal GC B cells are stringently selected to express a functional, high affinity BCR, the lost B-cell phenotype may be related to the origin of HRS cells from pre-apoptotic GC B cells: by losing the B cell–typical gene expression program, the HRS cell precursors may escape from the pressure to undergo apoptosis as "failed B cells." It should, however, be noted that further distinct subpopulations of GC B cells are currently being recognized (e.g., $CD30^+$ GC B cells), and it will be important to take these novel findings into consideration for a refinement of the cellular origin of HRS and LP cells.

The recent molecular biologic findings about HRS cells also offer some explanations for the typical and rather unique immunophenotypic heterogeneity of the HRS cells between cases and also among HRS cells of a given clone. The heterogeneity is likely due in part to different combinations of transforming events between HL cases. Moreover, the coexpression of multiple master regulators of different hematopoietic cell lineages (e.g., PAX5, ID2, Notch1) within one HRS cell clone may cause major fluctuations in gene expression between clone members by fluctuation of the competing transcription factors. Finally, because HRS cells are intimately interacting with multiple types of cells in their microenvironment, both by cellular interactions and through cytokines and chemokines, variations in the direct surrounding of HRS cells may cause differences in gene expression in these cells.

Further work is needed to fully understand the transforming events that lead to the generation of malignant HRS and LP cell clones, but with the availability of new methods, such as massively parallel sequencing of tumor genomes, it can be expected that major progresses will be made in the near future.

CHAPTER 74

HODGKIN LYMPHOMA: CLINICAL MANIFESTATIONS, STAGING, AND THERAPY

Dennis A. Eichenauer, Andreas Engert, and Volker Diehl

In his historic 1832 paper, "On Some Morbid Appearances of the Absorbent Glands and Spleen," Thomas Hodgkin presented the clinical history and postmortem findings of the massive enlargement of lymph nodes and spleens of seven patients. Hodgkin assumed that rather than an inflammatory condition or an infectious disease such as syphilis or tuberculosis, these pathologic findings more resembled an autonomous lymphatic process that started in the lymph nodes located along the major vessels in the neck, chest, or abdomen.

In 1865, Sir Samuel Wilks for the first time linked Thomas Hodgkin's name to the disease that he described as "Cases of the Enlargement of the Lymphatic Glands and Spleen (or Hodgkin's Disease)." He was also the first to describe Hodgkin lymphoma (HL)–associated B symptoms such as weight loss and fever. In 1878, Greenfield was the first to publish drawings of the pathognomonic giant cells, which later were named after Carl Sternberg (1898) and Dorothy Reed (1902), who contributed the first definitive microscopic descriptions of HL.

Because HL was frequently clinically associated with tuberculosis, for a long time it was considered to be a peculiar form of a granulomatous disease such as tuberculosis. Despite the very strong evidence for the malignant nature of HL over the past century, it has been only recently shown that Hodgkin and Reed-Sternberg (HRS) cells are definitely clonally expanding, pre-apoptotic, germinal center–derived B lymphocytes that resemble true malignant cells.[1-2] (See Chapter 73.)

The management of HL has undergone a paradigm shift as a result of the availability of effective first-line regimens inducing high remission rates, the use of combined chemoradiotherapy and the introduction of effective salvage chemotherapy followed by autologous stem cell transplantation (ASCT) in relapsed HL, and a more sensitive realization of the magnitude of treatment-related late effects. Future developments will be based on a better understanding of biologic prognostic factors and the implementation of PET imaging to allow a more individualized treatment approach. In addition, novel drugs used in combination with classical chemotherapy protocols may increase efficacy and decrease toxicity of HL treatment.

ETIOLOGY, EPIDEMIOLOGY, AND GENETICS

Incidence and Age of Onset

HL is a rare disease with an annual incidence of 2 to 3 cases per 100,000 persons in Europe and the United States. In industrialized countries, the onset of HL has a bimodal distribution, with a first peak occurring in the third decade and a second peak occurring after the age of 50 years. Because of more refined molecular, cytologic, and immunohistologic techniques offering sensitive discrimination between HL subtypes and non-Hodgkin lymphoma (NHL), the second peak seems to have disappeared, mainly because the lymphocyte-depleted subtype of HL was recognized more frequently as large B-cell lymphoma. Slightly more men than women (1.4:1) develop HL. Among the group of young adults, the most common subtype is nodular sclerosing HL (NSHL) (Fig. 74-1). The frequency of the mixed-cellularity HL (MCHL) subtype increases with age, whereas the incidence of the NSHL subtypes reaches a plateau in the group of young adults older than 30 years so that MCHL is the subtype most often observed in older patients. According to the World Health Organization (WHO) classification, the subtypes of lymphocyte-rich classic HL (LRCHL), nodular lymphocyte-predominant HL (NLPHL) and lymphocyte-depleted HL (LDHL) are less commonly diagnosed, with a frequency of 3% to 5% (LPHL and LRCHL, respectively) and less than 1% (LDHL) in Western countries (Table 74-1). Incidence of this disease varies greatly between developing and industrialized countries. In developing countries, the disorder occurs predominantly during childhood, and its incidence decreases with age, whereas in industrialized countries, young children are much less commonly diagnosed with HL compared with adolescents or young adults. In industrialized countries, there are associations for early birth order, low number of siblings and playmates, high level of maternal education, single-family dwellings during childhood, and occurrence of HL in younger patients.

Role of Epstein-Barr Virus in the Pathogenesis of Hodgkin Lymphoma

Several studies have suggested that the Epstein-Barr virus (EBV) might be a transforming agent in HL. Mueller and colleagues analyzed EBV titers in predisease sera and found enhanced EBV activation before the onset of HL. Patients with a history of EBV-related infectious mononucleosis had a twofold to threefold increased risk for the development of HL. Another study confirmed that patients with a serologically diagnosed infectious mononucleosis had a fourfold increased relative risk for EBV-positive but not EBV-negative HL. The estimated median incubation time from mononucleosis to EBV-positive HL was 4.1 years, making a causal association between mononucleosis-related EBV infection and the EBV-positive subgroup of HL likely in young adults.[3]

To substantiate the role of EBV in HL, a number of researchers investigated EBV in HRS cells using novel molecular techniques and found that EBV-DNA is more often present in the tumor cells of HL patients in developing than in industrialized countries. In Western countries, about 50% of all cases of classic HL are EBV-positive (i.e., carry the virus within the tumor cells) (Fig. 74-2), with 15% to 30% of NSHL cases being positive and up to 70% of MCHL subtypes harboring EBV-DNA. In comparison, 90% or more of HRS cells are positive for EBV in developing countries. It was also shown that an impaired immune status may contribute to the development of EBV-positive HL in older patients.

HRS cells in EBV-positive patients show an expression pattern of EBV-encoded genes resembling that found in endemic nasopharyngeal carcinoma or in a subset of T-cell lymphomas, called *type 2 latency*. This pattern includes expression of the EBV-latent genes LMP1, LMP2, and EBNA1. Recently, it was shown by three independent studies that EBV can rescue B-cell receptor (BCR)–deficient germinal center B cells from apoptosis, adding evidence that EBV plays a role in the malignant transformation in HL.

Because EBV is present in only half of the tumor cells in HL patients from the Western world, investigators were prompted to

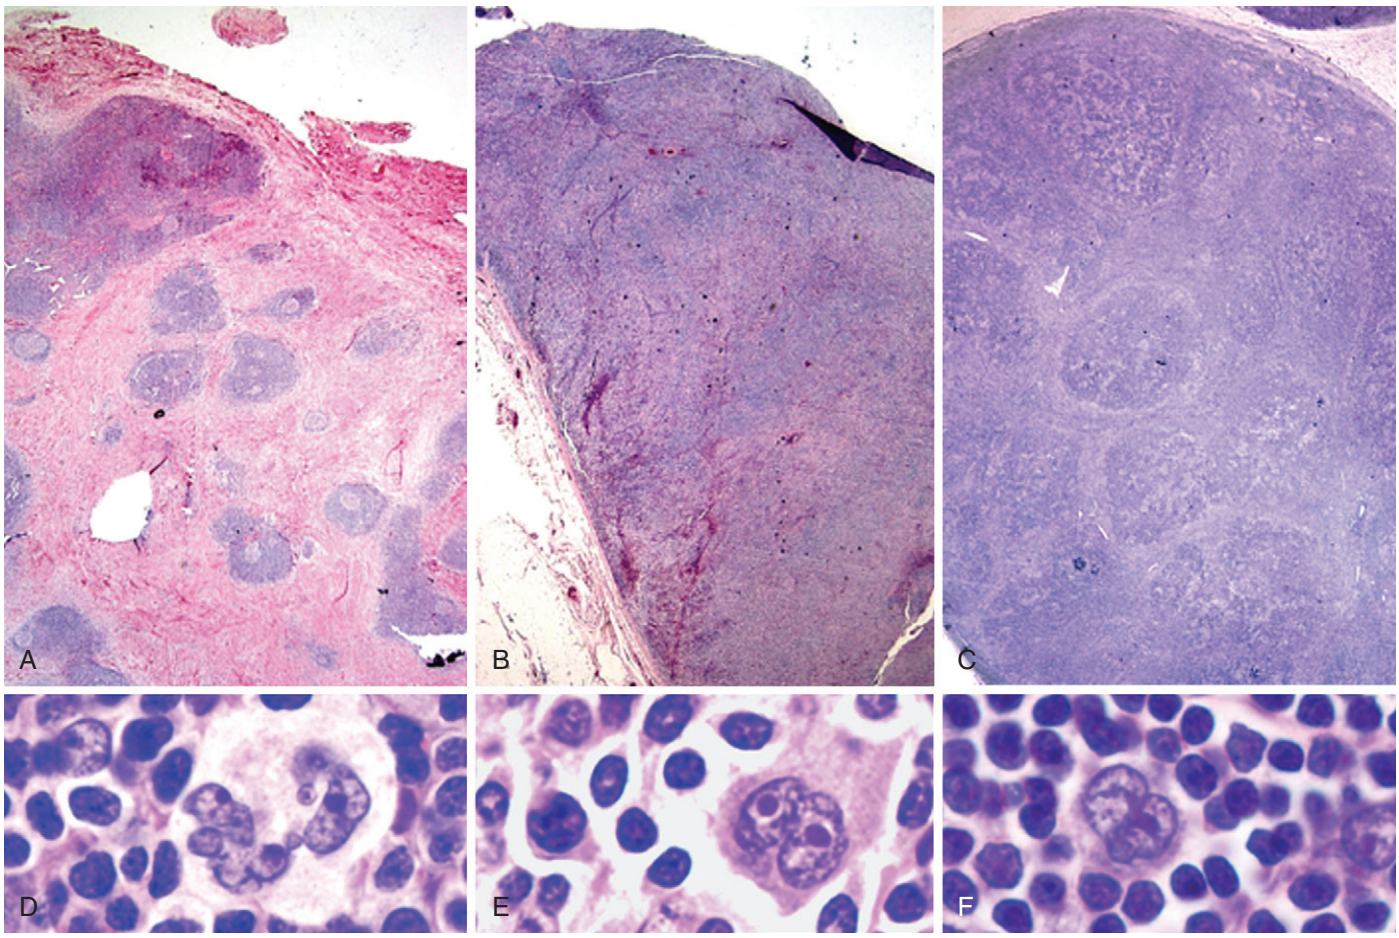

Figure 74-1 MORPHOLOGIC FEATURES OF DIFFERENT SUBTYPES OF HODGKIN LYMPHOMA. A low-power view of nodular sclerosing HL **(A)**, showing dense bands of fibrosis *(pink material)* dividing the node into cellular nodules. A similar low-power view of mixed cellular type **(B)** illustrating diffuse and patchy effacement of the normal lymph node architecture. In nodular lymphocyte predominance type **(C),** the node shows multiple vague expansile nodules. Sometimes these compress adjacent tissue and normal vasculature, giving the appearance of thin sclerotic bands, but this is not sclerosis as in the nodular sclerosing type. High-power illustrations of the associated neoplastic cells in these three variants. Lacunar cell variants **(D)** are the most prominent neoplastic cells in the nodular sclerosing type. These cells have lobulated nuclei and a clear space around the nucleus due to contraction of the cytoplasm in formalin-fixed tissue. More typical Reed-Sternberg cells can also be seen. In the mixed cellular type, classic mononuclear Hodgkin cells and binuclear Reed-Sternberg cells **(E)** are usually readily identified. In the nodular lymphocyte predominance type, the neoplastic cells are referred to as *LP cells* or *L&H (lymphocyte/histiocyte) cells* or *popcorn cells* because of their appearance **(F)**. In all types there are various numbers of reactive lymphocytes, plasma cells, histiocytes, eosinophils, and other acute inflammatory cells in the background.

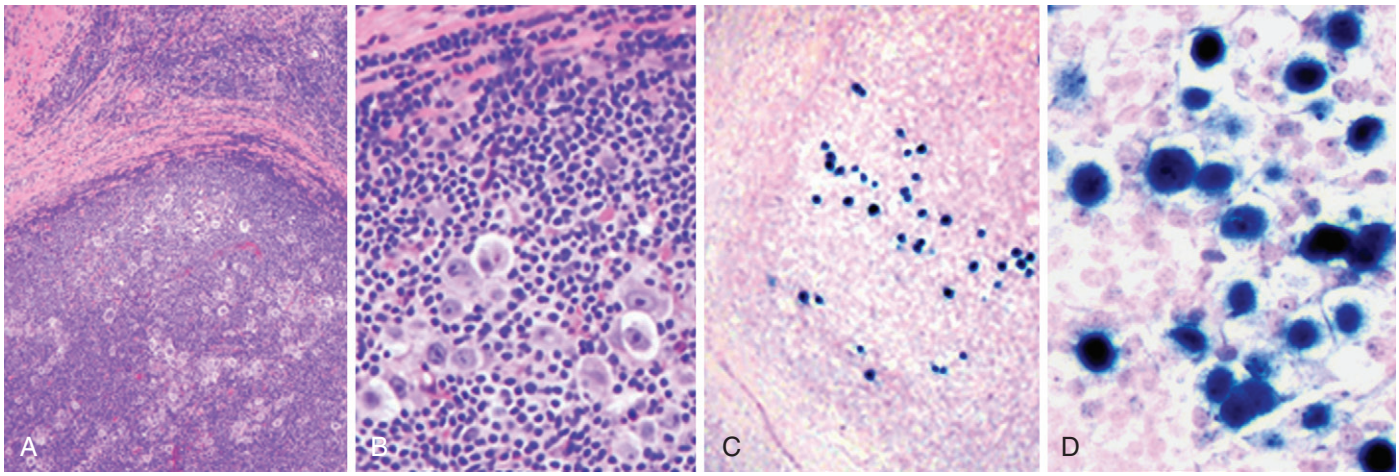

Figure 74-2 EBV DEMONSTRATED IN A CASE OF CLASSIC HODGKIN LYMPHOMA. Histologic sections **(A** and **B)** showing nodular sclerosing Hodgkin lymphoma with sclerotic bands, cellular nodules, and the HRS variant, lacunar cells. Epstein-Barr virus demonstrated by in situ hybridization by EBER (EBV-encoded RNA) identified by a black/blue reaction product, at low and high power **(C** and **D)**.

search for other viruses involved in the pathogenesis of HL. Although measles virus has been discussed to be associated with HL, the role of viruses other than EBV in the pathogenesis of HL remains uncertain. More specifically, despite initial reports that SV40 virus is present in a variety of lymphomas including HL, polyoma viruses were not detected in HL samples in follow-up studies.

Taken together, these data suggest that EBV is involved in the transformation process in EBV-positive HL cases. In EBV-negative cases, a "hit and run" mechanism was hypothesized, but evidence of EBV as a transforming agent in negative cases is scant.

Inheritance Pattern

In general, a family history of hematopoietic malignancy is associated with an approximately twofold increased risk to develop HL. More specifically, the risks of family members of patients affected by HL for developing the same disease are three to nine times those of the expected values. These observations led to the hypothesis that at least a portion of cases occur as an inherited disorder. Mack and colleagues found that of 179 monozygotic twin pairs with HL, both twins developed HL in 10 pairs, strongly supporting the idea of a genetic component in a subset of HL. Recent linkage studies correlated family or personal history of autoimmune or chronic inflammatory disease with the development of HL, suggesting that certain characteristics of the immune system might be important for the development of HL. However, familial HL is estimated to constitute only a minority of cases. No consistent mechanism of inheritance has been identified, and evidence for a genetic translocation unique to all cases of familial HL is lacking.

Hodgkin and Reed-Sternberg Cells and Their Origins

The affected tissue in HL is characterized by a heterogeneous infiltrate with typical mononucleated and multinucleated giant cells in an inflammatory background composed of stroma, lymphocytes, histiocytes, eosinophils, and monocytes. In classic HL (cHL), the giant cells are called *HRS cells,* and in NLPHL, they are called *lymphocyte predominant (LP) cells* (see Fig. 74-1). Typically, HRS cells represent only 0.1% to 1% of the affected tissue.

Because immunophenotyping did not lead to the identification of the origin of the HRS cells, molecular approaches were used to resolve this issue. Küppers was the first to show that HRS cells harbor somatically mutated clonal rearranged immunoglobulin (Ig) heavy chain genes by using single-cell polymerase chain reaction (PCR) methods on primary HRS cells.[2]

From these results, it was concluded that HRS cells were derived from germinal center B cells (Fig. 74-3). Amplification of identically rearranged and mutated Ig genes from different HRS cells showed they were clonal in origin—a key criterion of malignancy. HRS cells expand clonally within one affected lymph node, clonally disseminate in advanced-stage disease, and recur even after clinical complete remission (CR). Some studies indicate that in a small subset of HL, the HRS cells are probably of T-cell origin. In contrast, LP cells in NLPHL harbor ongoing mutations in their rearranged Ig genes and therefore seem to be malignant B cells at a different stage of maturation.

Table 74-1 Hodgkin Lymphoma Subtypes According to the WHO Classification

Nodular-sclerosing classic Hodgkin lymphoma
Mixed-cellularity classic Hodgkin lymphoma
Lymphocyte-rich classic Hodgkin lymphoma
Lymphocyte-depleted classic Hodgkin lymphoma
Unclassifiable classic Hodgkin lymphoma
Nodular lymphocyte–predominant Hodgkin lymphoma

Malignant Transformation of Hodgkin and Reed-Sternberg Cells

Despite significant progress in understanding the cellular origin of HRS cells, little is known about the mechanisms responsible for the initial transformation event. EBV has been identified as a virus with potential involvement in the transformation of a subpopulation of HL cases. Constitutive activation of nuclear factor–kappa B (NF-κB) seems to be a central mechanism that results in the exit of cells from the hostile environment of the germinal center and contributes to their proliferation and resistance to apoptosis.

Infected HRS cells express the EBV-encoded latent genes LMP1, LMP2, and EBNA1. Products of the latent genes have transforming capacity. LMP1, for instance, can transform primary B cells by mimicking the function of constitutively active CD40, a transmembrane receptor molecule of the TNF receptor family. Physiologically, CD40 ligation results in activation of a signaling cascade terminating in activation of the transcription factor NF-κB. NF-κB itself initiates transcription of proinflammatory and antiapoptotic genes. Constitutively, activation of NF-κB has been demonstrated to be a characteristic feature of HRS cells. Abrogation of constitutive NF-κB activation results in massive, spontaneous apoptosis of HRS cells by downregulation of an antiapoptotic signaling network, thereby providing evidence for its central role in the transformation and acquisition of the apoptosis-resistant phenotype.

SUMMARY OF MECHANISMS UNDERLYING MALIGNANT TRANSFORMATION

Although much has been learned about the derivation of the HRS cells, little is known about the basic mechanisms underlying malignant transformation of HL. The HRS cells in HL are derived from pre-apoptotic germinal center B cells in most cases, but in some cases, they are of T-cell origin. The expression of EBV-latent genes in EBV-positive cases (50%) may play a role in cellular transformation by upregulating the transcription factor NF-κB. The events underlying

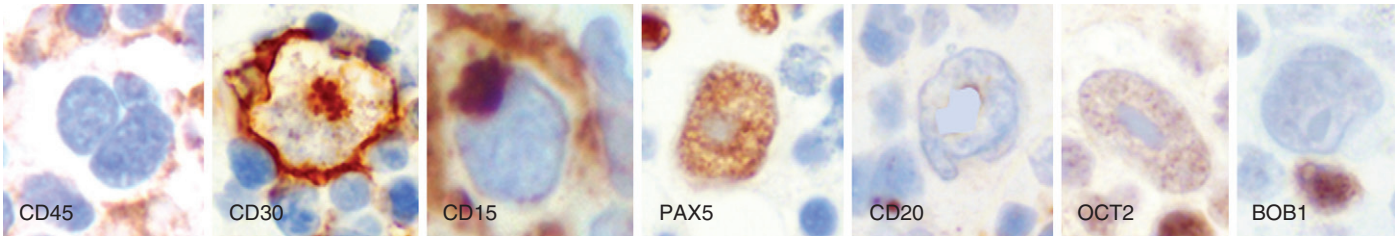

Figure 74-3 THE IMMUNOPHENOTYPE OF THE NEOPLASTIC CELLS IN CLASSIC HODGKIN LYMPHOMA. The cells typically are CD45-negative, CD30-positive, and CD15-positive with membranous and Golgi staining. The cells show nuclear staining for PAX5, a B-cell transcription factor, but the staining is usually weak compared with normal B cells. Typically, the cells are CD20-negative, but some cases can show partial or weak CD20. Last, the cells from classic Hodgkin lymphoma can weakly express one of the two other B-cell transcription factors: OCT2 and BOB1. They usually do not express both.

the transformation process in the EBV-negative cases, however, are still not understood. Several studies have focused on the apoptosis-resistant phenotype of HRS cells, and some data suggest that constitutively expressed FLICE-inhibitory protein (FLIP), a protein that inhibits FAS-mediated apoptosis, contributes to apoptosis resistance in HL. Genetic instability is a typical feature of HRS cells, and studies point to distinct genetic imbalances rather than subtile genetic alterations such as point mutations or microsatellite instability. Besides NF-κB, other transcription factors are deregulated in HRS cells, contributing to the lost B-cell identity of malignant cells in HL. The discovery that the HRS cells themselves contribute to the ineffective immune response by expressing immunosuppressive cytokines or by expressing chemokines that predominantly attract Th2 lymphocytes that are incapable of cell killing has widened our understanding of the environmental cross talk of these peculiar cells.

DIAGNOSIS AND STAGING

From the beginning, it was postulated that HL spread from one lymph node area by contiguity to adjacent lymph node chains. Only in the middle of the 20th century was this knowledge used by investigators such as Peters, Kaplan, Tubiana, and Musshoff for the development of strategies for the treatment of this disorder.

The applicability of new radiologic techniques and the information derived from routine exploratory staging laparotomies have provided important insights into the presentation and evolution of HL. Although there is strong evidence that HL starts in a single group of lymph nodes and then spreads by the lymphatic route, mounting data suggest that the gradually more aggressive tumor cells tend to disseminate through the bloodstream rather early and disseminate to organs such as bone marrow, liver, and lung. For the initial diagnosis of HL, an excisional biopsy of a suspicious lymph node should be performed. Assessment of the bone marrow is important for staging and for an evaluation of the normal bone marrow cells before therapy. Bone marrow involvement occurs in less than 5% of patients.

The extent of HL can be classified using the four-stage Ann Arbor classification. The absence (A) or presence (B) of systemic symptoms (e.g., fever, night sweats, and weight loss) further characterizes the severity of disease. The Cotswolds classification is a modification of the Ann Arbor classification, using information from staging and treatment gathered over the past 20 years. This classification was proposed in 1989 during a meeting held in the Cotswolds, England. Information about prognostic factors such as size of the mediastinal mass, the presence of bulky nodal disease, and the extent of subdiaphragmatic disease is included in this classification.

The staging procedures recommended for determining the extent of disease have become less invasive in recent years. Staging laparotomy and splenectomy are no longer used. Computed tomography (CT) of neck, chest, abdomen, and pelvis is routinely performed in the diagnostic evaluation of a patient with HL.

Two thirds of patients with newly diagnosed HL have radiographic evidence of intrathoracic involvement. A *large mediastinal mass* has been arbitrarily defined as a mass in which the ratio is greater than one third for the largest transverse diameter of the mediastinal mass over the transverse diameter of the thorax at the diaphragm on a standing posteroanterior chest radiograph. Alternatively, others have defined extensive mediastinal disease as greater than 35% of the thoracic diameter at T5-6 or wider than 5 or 10 cm.

Gallium 67 scintigraphy, previously used in evaluating the mediastinum or in the evaluation of residual masses in HL patients after treatment, has been replaced by FDG-PET. According to the international harmonization project, FDG-PET can be used to improve staging techniques at initial diagnosis by detecting lesions not detected by CT, to assess tumor response while on treatment, and to evaluate residual tumor masses at the end of treatment, allowing discrimination between active lymphoma and fibronecrotic tissue.[4]

When FDG-PET is used in addition to conventional imaging techniques for the initial workup of patients, approximately 10% of HL patients are up-staged and another 10% down-staged but it remains unclear whether patients would benefit from a subsequent change of the treatment plan. Therefore the value of FDG-PET for initial staging of HL patients is limited. When assessing early tumor response rates in HL patients after two or three cycles of chemotherapy, Hutchings and Gallamini found a significant correlation between the PET results and the clinical outcome of patients in terms of progression-free survival (PFS) and overall survival (OS).[5] Whether such an early PET response will be useful to tailor therapies more individually in the future needs to be clarified by prospective trials currently ongoing worldwide.

If PET is used at the end of treatment, it shows an excellent negative predictive value. In the HD15 trial from the German Hodgkin Study Group (GHSG), patients with advanced HL who had residual lesions larger than 2.5 cm after chemotherapy underwent PET examination. Patients with a positive PET received additional localized radiation, whereas those patients with a negative PET did not receive further treatment. The negative prognostic value (defined as the proportion of PET-negative patients without progression, relapse, or the need for radiation within 12 months) was 94.6%. Thus PET-guided radiation in patients with advanced HL was adopted as standard within the GHSG.

CLINICAL FEATURES

Patients with NSHL or MCHL have a central pattern of lymph node involvement (e.g., cervical, mediastinal, paraaortic). In most patients with cHL, primary lymphadenopathy occurs in the left cervical or supraclavicular region or in the mediastinum. NSHL patients more often have a supradiaphragmatic onset of disease. MCHL patients present with smaller disseminated nodes and predominantly subdiaphragmatic nodes or organ involvement. In contrast, certain nodal chains (e.g., mesenteric, hypogastric, presacral, popliteal) are seldom involved. Patients with NLPHL typically present with involved peripheral nodes in the cervical, submandibular, axillary, or inguinal region. NLPHL is mostly diagnosed in early stages. B symptoms and involvement of the spleen or other organs rarely occur. The spleen is involved more frequently in patients with adenopathy below the diaphragm, systemic symptoms and MCHL histology. Involvement of the liver is rare and mainly occurs with concomitant splenic involvement. Infiltration of the bone marrow at diagnosis is uncommon, usually focal, and almost always associated with extensive disease, systemic symptoms, and unfavorable histology.

Bulky lymph node involvement or a contiguous collection of smaller lymph nodes (>10 cm in diameter) may result in regional complications such as vascular, tracheal, bronchial, or gastrointestinal compression or obstruction. Invasion of adjacent anatomic regions such as the lung, pericardium, pleura, chest wall, or bone can occur in patients with HL. Effusions of the pericardium, pleural cavity or peritoneal cavity are often associated with extranodal involvement and invasive growth into neighboring structures. Despite a large mediastinal mass, superior vena cava syndrome is seldom observed; if it occurs, it is often associated with venous thrombosis.

Compared with NHL, bulky infradiaphragmatic lesions with obstructive symptoms are rare in HL. Spleen involvement is often subclinical and sometimes hard to diagnose with modern imaging techniques. Tumor involvement is not necessarily associated with splenic enlargement; a small spleen can have diffuse HL involvement.

Hematopoietic spread to organs is mainly seen in the lung, liver, bone marrow, and bone, and it must be distinguished from disease invasion into adjacent organs by an extranodal tumor that penetrates the capsule of a lymph node. Skin involvement is seen very rarely and can appear as small, opaque, or red papules or as ulcerating lesions. Involvement of the central nervous system can occur by extension from nodes within the paraaortic region through the intervertebral foramina, manifesting as neurologic symptoms and pain.

A considerable number of undiagnosed patients with HL present with systemic symptoms before the discovery of enlarged lymph nodes. Typical symptoms include fever, drenching night sweats, and

weight loss (i.e., B symptoms). The characteristic HL-associated fever (i.e., Pel-Ebstein type) occurs intermittently and recurs at variable intervals over several days or weeks. Fever and drenching night sweats are identified in 25% of all patients at the time of initial presentation, increasing to 50% of patients with more advanced disease. Other nonspecific symptoms include pruritus, fatigue, and the development of pain shortly after drinking alcohol. This pain is usually transient at the site of nodal involvement and may be severe. Pruritus, although not a defined B symptom, may be an important systemic symptom of disease, although it affects less than 20% of patients. It often occurs months or even a year before the diagnosis of HL. The underlying pathophysiologic mechanisms leading to pruritus are unknown, but possible causes include an intrinsic production of cytokines such as growth factors by the HRS cells and an autoimmune reaction in which a number of cytokines are activated by tumor lysis.

CHOICE OF TREATMENT

Prognostic Factors and Treatment Groups

Prognostic factors define the likely outcome of the disease of an individual patient at diagnosis allowing selection of appropriate treatment strategies. Despite an enormous effort to define clinically relevant and generally acceptable prognostic factors, there are still two major methods for dividing HL patients according to a risk- or prognosis-adapted therapeutic approach: stage and systemic symptoms. A third factor meets general transatlantic acceptance: massive local tumor burden (i.e., bulky disease >10 cm in diameter). Prognostic factors are rarely the subject of specific clinical studies but are recognized and evaluated using data from large cohorts of uniformly treated, well-documented, and reliably followed patients, usually from large clinical trials.

In the United States, some centers still treat HL patients according to the traditional separation of early stages (stage I-IIA), representing about 45% of newly diagnosed patients, and advanced stages (III-IV, A and B, or any stage with bulky disease >10 cm in diameter or B symptoms), representing about 55% of newly diagnosed patients. Patients with early-stage disease are treated with combined-modality strategies. Patients with advanced-stage disease are assigned to intensive chemotherapy protocols, sometimes followed by adjuvant radiotherapy.

The European Organization for Research and Treatment of Cancer (EORTC), in the H1 and H2 trials, identified additional prognostic factors that are now used to assign clinical stage I or II patients to a more unfavorable-prognosis group. The EORTC has, since 1982, defined clinical stage I or II (supradiaphragmatic only) patients as having an early unfavorable prognosis HL if any of the following factors is present: age older than 50 years, asymptomatic with an ESR higher than 50 mm/h, B symptoms with an ESR higher than 30 mm/h, and a large mediastinal mass (Table 74-2). In previous trials, stage II disease with MCHL or LDHL histology and number of involved regions had also been counted as adverse factors.

The GHSG has, since 1988, assigned clinical stage I or II patients to an intermediate group if they have any of the following adverse factors: large mediastinal mass (>⅓ of maximum thoracic diameter), three or more involved nodal areas, elevated ESR, and localized extranodal infiltration (Table 74-2). It can be difficult to distinguish consistently between extranodal lesions and stage IV disease, so various assessments of the prognostic value of this feature have been obtained by different investigators.

Currently, the following general treatment strategies are widely used in the United States and in Europe:

1. Early stages, favorable: combined-modality approaches (2-4 cycles of chemotherapy plus involved-field radiation)
2. Early stages, unfavorable (intermediate): combined-modality approaches (4-6 cycles of chemotherapy plus involved-field radiation)
3. Advanced stages: extensive chemotherapy (6-8 cycles) with or without consolidating localized radiation

Table 74-2 Allocation of Hodgkin Lymphoma Patients to Treatment Groups

Treatment Group	EORTC/GELA	GHSG
Limited-stage patients	CS I-II without risk factors (supradiaphragmatic)	CS I-II without risk factors
Intermediate-stage patients	CS I-II with ≥1 risk factors (supradiaphragmatic)	CS I, CS IIA with ≥1 risk factors CS IIB with risk factors C/D, but not A/B
Advanced-stage patients	CS III-IV	CS IIB with risk factors A/B, CS III/IV
Risk factors	(A) Large mediastinal mass (B) Age ≥50 years (C) Elevated ESR (D) ≥4 nodal areas	(A) Large mediastinal mass (B) Extranodal disease (C) Elevated ESR (D) ≥3 nodal areas

An attempt has also been made to identify very good risk and very poor risk subgroups. The EORTC has investigated the use of localized radiotherapy in a "very favorable subgroup" of early-stage patients. Inclusion criteria were stage IA disease for female patients younger than 40 years and NSHL or NLPHL histology without an elevated ESR or large mediastinal mass. However, the failure rate was 29% at 6-year follow-up, and this policy was abandoned. Similarly, advanced-stage patients at particularly high risk for failure were treated with early high-dose chemotherapy (HDCT) with autologous stem cell transplantation (ASCT). Currently, only patients who relapse after first-line treatment receive HDCT followed by ASCT. HDCT/ASCT is not included in standard treatment strategies for initially diagnosed HL.

The EORTC includes in its advanced-stage cohort stage III and IV patients only, without regard to other factors, as did the U.S. National Cancer Institute and several U.S. cooperative groups. Certain other trial groups also include stage I-II patients in the advanced-stage group, if they have B symptoms or bulky disease. The GHSG includes both stage III-IV patients and patients with stage IIB disease and a large mediastinal mass and/or E-lesions in the advanced-stage cohort (Table 74-2). The gradual shift towards more intensive therapy is based on the incorporation of prognostic factors into treatment algorithms.

Prognostic Factors for Advanced-Stage Hodgkin Lymphoma

International consensus about longer and better-controlled follow-up periods with the observation of a greater frequency of treatment failure events has permitted the identification of more conclusive and generally applicable prognostic factor analyses for advanced-stage disease. The International Prognostic Factor Project produced an International Prognostic Score (IPS), which, although not necessarily completely comprehensive, is widely accepted.

All of the factors included in the IPS were shown to be highly significant in a multivariate analysis of data from 5141 patients, and their prognostic power was confirmed in an independent sample. All seven factors were associated with similar relative risks of between 1.26 and 1.49. It was recommended that these factors should be combined into a single score by counting the number of adverse factors resulting in an integer prognostic score between 0 and 7. However, even patients with five or more factors (7% of cases) had a 5-year failure-free rate of more than 40%. The best failure-free rate was close to 80% for patients with at most one adverse factor (29%

of cases), suggesting that a group of advanced-stage patients with a relatively favorable prognosis could be recognized (1618 patients included in the final analysis for freedom from treatment failure according to whether the prognostic score was 0 to 2 or 3 or higher).[6]

A number of other factors have been shown to correlate with prognosis in advanced stages, but their independent importance has not been proven because of conflicting results or lack of validation in a large independent data set. These include pathologic grade in NSHL, the amount of tissue eosinophilia, inguinal involvement, serum lactic dehydrogenase concentration, and beta-2 microglobulin level.

In conclusion, the three-level scheme of division into early favorable, early unfavorable (intermediate), and advanced-stage cases remains a suitable instrument to tailor therapy. Because clinical and biologic factors do not discriminate the 10% to 15% of advanced-stage patients who will progress or experience an early relapse (<12 months), biologic molecular parameters are urgently needed to save most patients from overtreatment or intensify treatment for patients resistant to the best modern treatment modalities. There is hope that current approaches using on-treatment imaging techniques such as PET, gene expression profiles of primary tumor material, individual drug metabolism, or cytokine profiles of serum samples will detect patterns that distinguish low-risk from standard-risk and poor-risk patients.

EARLY-STAGE HODGKIN LYMPHOMA

Early Favorable Disease

The treatment of early-stage HL is changing. In the 1990s, extended-field irradiation was considered standard treatment. However, because of the high relapse rate and the increased frequency of long-term effects, the use of extended-field radiotherapy has been abandoned by most study groups. Instead, a brief chemotherapy combined with involved-field irradiation is the current standard of care for early favorable HL.

Extended-field radiotherapy alone produces CR in 90% to 98% of patients with early favorable HL. Unfortunately, 30% to 40% of those patients relapse, but salvage chemotherapy or combined-modality treatment yields remissions in most of these cases. As a result, approximately 75% to 85% of patients with early favorable disease who receive extended-field radiotherapy as first-line treatment are alive after 10 years.[7]

Combined-Modality Treatment With Extended-Field Irradiation Versus Extended-Field Radiotherapy Alone

To reduce the high relapse rates observed with radiotherapy alone, combined-modality therapies were introduced and compared with radiotherapy alone in patients with early favorable HL. The HD7 trial (1994-1998) of the GHSG randomized 650 patients with early favorable HL to extended-field radiation alone or to two courses of ABVD (i.e., doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine) (Table 74-3) and extended-field radiation therapy. The final analysis after a median follow-up of 87 months showed an advantage in freedom from treatment failure (FFTF) in the patients receiving ABVD (88%) compared with those treated with irradiation alone (67%, P <0.0001) (Fig. 74-4). Probably because of effective salvage therapy, overall survival (94% and 92%) did not differ between the two treatment arms.[7]

Results were similar in an American Intergroup phase III trial comparing three cycles of doxorubicin (Adriamycin) and vinblastine (AV) plus subtotal lymphoid irradiation with subtotal lymphoid irradiation alone in clinical stage IA-IIA patients with supradiaphragmatic disease that did not undergo staging laparotomy. The trial had to be closed after the second interim analysis because of a significantly superior failure-free survival rate for patients in the combined-modality arm (94% versus 81%, respectively, at a median follow-up of 3.3 years). However, the two previously described studies used extended-field radiotherapy and did not address the issue of whether radiation therapy could be reduced safely when coadministering chemotherapy.

Table 74-3 The ABVD Regimen

Drug	Dose	Route	Schedule
Doxorubicin	25 mg/m^2	IV	Days 1 + 15
Bleomycin	10 mg/m^2	IV	Days 1 + 15
Vinblastine	6 mg/m^2	IV	Days 1 + 15
Dacarbazine	375 mg/m^2	IV	Days 1 + 15

Recycle day 29

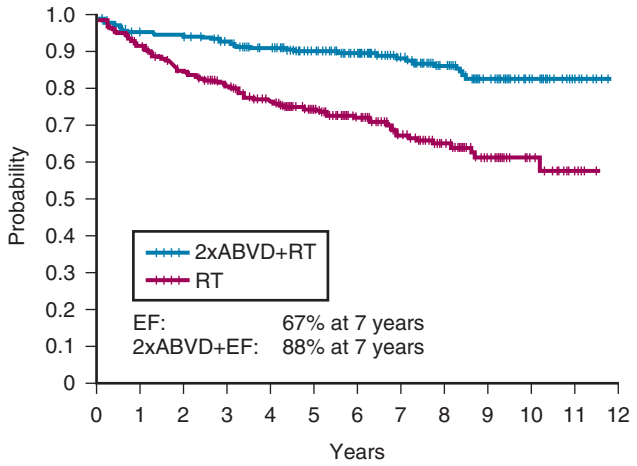

Figure 74-4 FREEDOM FROM TREATMENT FAILURE AMONG PATIENTS TREATED WITHIN THE GHSG HD7 TRIAL FOR EARLY FAVORABLE HODGKIN LYMPHOMA. *Blue,* Combined-modality treatment (2 cycles of ABVD plus extended-field radiotherapy). *Purple,* Radiotherapy alone (extended-field radiotherapy). *(Engert A, Franklin J, Eich HT, et al: Two cycles of doxorubicin, bleomycin, vinblastine, and dacarbazine plus extended-field radiotherapy is superior to radiotherapy alone in early favorable Hodgkin's lymphoma: Final results of the GHSG HD7 trial,* J Clin Oncol *25:3495, 2007.)*

Combined-Modality Treatment With Involved-Field Radiotherapy Versus Extended-Field Radiotherapy Alone

Randomized trials of combined-modality therapy have been based on the premise that this approach results in a very high freedom from recurrence rate and that this high degree of efficacy can even be maintained when using less toxic chemotherapy and radiation approaches. In the EORTC H7F trial (333 favorable patients), six cycles of the EBVP regimen (i.e., epirubicin, bleomycin, vinblastine, and prednisone) plus involved-field irradiation were compared with mantle and para-aortic-splenic nodal irradiation for favorable-prognosis clinical stage IA-IIA patients. At 10 years, the event-free survival rate was significantly better for patients on the combined-modality arm compared with those receiving radiation alone (88% versus 78%, P = 0.01). Survival rates were similar (92%). Because the H7U trial showed that EBVP is less efficient than a hybrid of MOPP (mechlorethamine, vincristine [Oncovin], procarbazine and prednisone) and ABVD, the latter regimen was used in subsequent studies.

The EORTC H8F trial (1993-1998) compared three cycles of MOPP/ABV and involved-field irradiation against mantle and para-aortic-splenic irradiation for favorable-prognosis clinical stage IA-IIA patients. Because relapse-free survival differed significantly between the two treatment arms (98% versus 74%; P <0.001), it was concluded that combined-modality treatment was the new gold standard of therapy. Taken together, this EORTC trial was the first to demonstrate that subtotal nodal irradiation could be safely replaced by a combined-modality regimen, because reduced radiotherapy (involved-field radiotherapy) in combination with chemotherapy was shown to be superior to subtotal nodal irradiation.[8]

With the objective of reducing acute toxicity and chronic morbidity, Horning and colleagues developed a presumably less toxic chemotherapy regimen of vinblastine, bleomycin, and methotrexate (VBM), which was tested in a randomized trial of pathologic stage IA-IIB and pathologic stage IIIA patients. The trial compared subtotal nodal/total nodal irradiation with involved-field irradiation (44 Gy) followed by VBM. The freedom from disease progression at 5 years favored involved-field irradiation and VBM (95%) over subtotal nodal/total nodal irradiation alone (70%). No differences were seen in OS. The British National Lymphoma Investigation (BNLI) has confirmed the efficacy of VBM with involved-field irradiation, but in their experience, this approach produced unacceptable pulmonary and hematologic toxicity.

Involved-Field Radiation Dose in Combined-Modality Treatment

In the multicenter international HD10 trial of the GHSG, 1370 patients were randomized to two or four cycles of ABVD followed by 20 or 30 Gy of involved-field radiation therapy. At 5 years, FFTF and OS rates were very similar in all treatment arms; thus the least-toxic approach (two cycles of ABVD followed by 20 Gy of IF-RT) was adopted as the novel standard for early favorable HL.[9]

The GHSG follow-up trial for patients with early favorable HL, HD13, was designed to determine whether the rather toxic components of the ABVD regimen of bleomycin (lung) and dacarbazine (gastrointestinal) can safely be eliminated in combined-modality treatment schedules. The data safety monitoring committee closed the AV and the ABV arm prematurely in 2005 and 2006 due to a fourfold increase in HL-related events compared with ABVD and AVD. Randomization into the other arms was continued as planned until 2009. Thus final results of the trial are pending.

Two randomized trials tested chemotherapy-only approaches for early-stage patients. The EORTC/GELA H9F trial (n = 783) evaluated doses of 36 Gy, 20 Gy, or no radiation to involved sites in patients who have achieved complete remission after six cycles of EBVP (n = 591). The final analysis with arm comparison showed higher relapse rates than expected in the chemotherapy-only arm, which had to be closed early. The event-free survival at 4 years was 87%, 84%, and 70% for 36 Gy, 20 Gy, and no radiation therapy, respectively (P <0.001) showing that involved-field radiation could not be skipped when combined with a mild chemotherapy regimen. Although data are not yet mature, it was postulated that a dosage of 20 Gy is equally efficient as 36 Gy in these patients.

Meyer and colleagues published results of a trial conducted by the National Cancer Institute of Canada Clinical Trials Group and the Eastern Cooperative Group. Patients with stage I-IIA were allocated to a favorable and an unfavorable cohort (inclusion criteria: age >40 years, ESR >50 mm/h, mixed-cellularity or lymphocyte-depleted histology, and >4 sites of involvement) before random assignment to ABVD as single modality or a radiotherapy-containing treatment. Patients in the chemotherapy-only group received up to six cycles of ABVD. Patients in the radiotherapy group were treated with subtotal nodal irradiation only or two cycles of ABVD and subtotal nodal irradiation, if allocated to the favorable or the unfavorable cohort, respectively. There was a statistically significant difference in terms of freedom from progression in favor of the radiation-containing regimen (93% versus 87%), but rates for event-free survival and OS did not reach statistical significance at a median follow-up time of 4.2 years. It might be speculated that the reduced freedom from progression rate for the chemotherapy-only arm will be outweighed by a reduced rate of long-term toxicities and secondary malignancies. This needs to be confirmed in a longer follow-up.

Recommendations and Future Directions for Early Favorable Hodgkin Lymphoma

Current clinical trials are evaluating the use of alternative chemotherapy combinations, shortened courses of chemotherapy, chemotherapy with smaller radiation fields or lower radiation doses, and chemotherapy without radiation therapy. Fortunately, HL-related death of patients with early favorable disease is unusual, and OS is not a useful parameter to evaluate midterm results in early-stage HL. Current trials should be judged by freedom from first recurrence rates and acute morbidity. On the basis of the available data, it can be concluded that patients with early favorable HL benefit from a short course of ABVD chemotherapy in combination with involved-field radiotherapy. Although there is some evidence that radiotherapy might not be necessary for those patients that achieve a CR after two courses of ABVD chemotherapy, it is still advisable to treat all patients with early favorable HL with a combined-modality regimen since long-term results on patients treated with chemotherapy only are pending. Ongoing studies using PET after two courses of ABVD and giving involved-field radiotherapy only to PET-positive patients (e.g., the GHSG HD16 trial) will demonstrate whether consolidative radiotherapy is necessary in case a metabolic CR is achieved after two cycles of ABVD.

Early Unfavorable Disease

It is generally accepted that early unfavorable HL should be treated with a combination of chemotherapy and radiotherapy. However, the prognostic impact of a single risk factor, the optimal chemotherapy regimen, the number of chemotherapy cycles, the field sizes, and the dosage of radiation within these fields are subjects of debate.

Trials to Identify the Best Chemotherapy Regimen

Based mainly on trial results from advanced HL, ABVD has also become the standard regimen for clinical stage I-II patients. In clinical trials, ABVD was thus compared with more intense regimens. The GHSG HD11 trial compared four cycles of ABVD with four cycles of BEACOPP (i.e., bleomycin, etoposide, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), procarbazine, and prednisone) in baseline dosage followed by involved-field radiotherapy at a dose of 20 or 30 Gy. The final results of the HD11 trial were published in 2010. FFTF after $BEACOPP_{baseline}$ was superior compared with that observed after ABVD when chemotherapy was followed by 20 Gy of involved-field radiotherapy. In contrast, no significant outcome differences between both chemotherapy protocols were detected in patients who received a 30 Gy radiation dose. Treatment-related toxicity was more frequently observed with $BEACOPP_{baseline}$. As a direct consequence, $BEACOPP_{baseline}$ was not adopted as new standard chemotherapy for early unfavorable HL.

Interim results of the EORTC H9U trial were similar. In this study, patients were randomized into three treatment arms consisting of four cycles of ABVD, six cycles of ABVD, or four cycles of $BEACOPP_{baseline}$, each followed by 30 Gy of involved-field radiotherapy. An interim analysis at a median follow-up of 4 years showed no significant differences regarding event-free survival and OS between the treatment arms while increased toxicity was observed with $BEACOPP_{baseline}$.

Significant outcome improvements in patients with early unfavorable HL were seen after the introduction of the $BEACOPP_{escalated}$ protocol (Table 74-4) in the treatment of these patients within the

Table 74-4 The BEACOPP$_{escalated}$ Regimen

Drug	Dose	Route	Schedule
Bleomycin	10 mg/m^2	IV	Day 8
Etoposide	200 mg/m^2	IV	Day 1-3
Doxorubicin	35 mg/m^2	IV	Day 1
Cyclophosphamide	1250 mg/m^2	IV	Day 1
Vincristine	1,4 mg/m^2 max. 2 mg	IV	Day 8
Procarbazine	100 mg/m^2	PO	Day 1-7
Prednisone	40 mg/m^2	PO	Day 1-14
G-CSF		Subcutaneous	From Day 8

Recycle day 22

GHSG HD14 trial. Patients were randomized to either four cycles of ABVD followed by 30 Gy of involved-field radiotherapy or a more intensified treatment protocol consisting of two cycles of BEACOPP$_{escalated}$ followed by two cycles of ABVD ("2+2") and the same radiotherapy. A preplanned interim analysis including 1010 patients at a median observation of 3 years revealed a significant superiority in FFTF for the 2+2 arm so that randomization for the trial was closed prematurely. The final analysis of HD14 including 1623 patients confirmed these results. At 5 years, the FFTF rate among patients who received the intensified 2+2 chemotherapy was significantly superior to that among patients who received four cycles of ABVD (94.7% versus 89.3%).

Radiation Field and Dose

In preceding studies, the GHSG randomized responding patients with early unfavorable disease to dosage of 40 Gy of extended-field irradiation or 20 Gy of extended-field irradiation plus 20 Gy of involved-field radiotherapy (HD1 trial) with no outcome difference. In the follow-up trial (HD5), patients received 30 Gy of extended-field irradiation plus 10 Gy to sites of bulky disease. These trials demonstrated that radiation dose in the extended field can safely be reduced to at least 30 Gy (with 10 Gy delivered to bulky tumors) when given after two cycles of alternating ABVD and COPP (i.e., cyclophosphamide, vincristine [Oncovin], procarbazine and prednisone). Similarly, other groups have aimed at improving combined-modality treatment for HL patients with early unfavorable disease. The cooperative study reported by Zittoun and colleagues compared six cycles of MOPP sandwiched around 40 Gy of radiotherapy applied in an involved-field or extended-field technique. No differences in terms of disease-free survival and OS were observed.

An Italian study headed by the Milan group enrolled patients in a randomized study comparing subtotal nodal irradiation with involved-field irradiation after four cycles of ABVD. At a median follow-up of 12 years, treatment outcomes were very similar in both arms (freedom from progression rates of 94% and 93%; survival rates of 96% and 94%, respectively).

In their H8U trial, the EORTC compared six cycles of MOPP/ABV plus 36 Gy of involved-field irradiation, four cycles MOPP/ABV plus 36 Gy of involved-field irradiation, and four cycles of MOPP/ABV plus subtotal lymphoid irradiation. At a median follow-up of 92 months, there were no differences among the three arms in terms of response rates, failure-free survival, and OS, leading to the conclusion that four cycles of chemotherapy followed by involved-field radiation should be the standard of care for patients with early unfavorable HL.[8]

The question of whether radiation fields can be reduced to the involved field after adequate chemotherapy was also the subject of the GHSG HD8 trial. This trial compared 30 Gy of extended-field irradiation plus 10 Gy to sites of bulky disease (>5 cm in diameter) with 30 Gy of involved-field radiotherapy plus 10 Gy to bulky disease sites after two alternating cycles of COPP/ABVD. Between 1993 and 1998, 1204 patients were randomized. The median observation time was 54 months. The OS rate for all eligible patients was 91%, and the FFTF rate was 83%. Comparisons of both arms showed similar rates for freedom from treatment failure (86% and 84%) and OS at 5 years (91% and 92%). No significant differences were found between the two arms in terms of complete remission, progressive disease, relapse, death, and secondary neoplasias. In contrast, acute side effects (including leukopenia, thrombocytopenia, nausea, and gastrointestinal and pharyngeal toxicity) occurred more frequently in the extended-field arm, so four cycles of chemotherapy plus 30 Gy of involved-field radiotherapy was adopted as standard of care within the GHSG.

Recommendations and Future Directions of Early Unfavorable Hodgkin Lymphoma

The outcome of treatment for patients with early unfavorable HL has improved dramatically in the past three decades. This results primarily from the use of combined-modality therapy, because radiation therapy alone or chemotherapy alone historically was associated with recurrence rates of approximately 50%. Four cycles of chemotherapy followed by 30 Gy of involved-field radiotherapy is a new standard for patients with unfavorable-prognosis early-stage HL. Most clinical trials are exploring new combinations of more effective chemotherapy and reduced radiation doses to determine optimal treatment, with the aim of decreasing late morbidity and mortality while maintaining a high probability of freedom from recurrence. Whether four to six cycles of chemotherapy without irradiation—at least in patients with complete metabolic response after chemotherapy as assessed by FDG-PET—can produce long-lasting remissions has not been determined. Trials such as the ongoing HD17 trial are addressing this issue.

ADVANCED-STAGE HODGKIN LYMPHOMA

Treatment Strategies

MOPP: Pioneer Combination Therapy

Until the middle of the 20th century, patients with advanced stages of HL were considered incurable. With the advent of more effective drugs, DeVita and colleagues at the National Cancer Institute were the pioneers who paved the way for the incredible success of modern chemotherapy in oncology by achieving a CR rate of 80% and cure in more than 50% among advanced-stage HL patients with the drug combination MOPP.

Despite the promising initial results with MOPP therapy, many investigators used alternative regimens to improve the efficacy or/and reduce toxicity. The omission of single drugs, such as the alkylating agents nitrogen mustard or procarbazine, from the MOPP regimen was associated with inferior CR rates, as shown by the Cancer and Leukemia Group B (CALGB). Therefore, at that time, the four-drug principle was considered the standard with which any other drug combination had to be compared.

ABVD: Second Combination Regimen

Despite great accomplishments with MOPP and MOPP-like regimens, there were major drawbacks. Between 15% and 30% of the patients did not obtain CR, and only about 50% of patients could be cured. The use of MOPP was associated with significant acute toxicity and with an increased risk for sterility and acute leukemia because of the alkylating agents included in this schema.

In 1975, Bonadonna and colleagues introduced the ABVD regimen for the treatment of patients who had failed MOPP therapy. Vinblastine had demonstrated high activity as a single agent and lacked cross-resistance with vincristine. Doxorubicin and bleomycin

were also very active drugs and produced objective responses in about 50% of patients. Dacarbazine was added because it was active as a single agent and showed synergism with doxorubicin.

The Milan group compared MOPP and ABVD, using three cycles of each drug combination, followed by extended-field irradiation and three additional cycles of the same chemotherapy regimen. The comparison demonstrated a significant superiority for ABVD, with freedom from progression rates of 63% for MOPP compared with 81% for ABVD.

The pivotal CALGB trial of treatment for advanced HL, which compared MOPP, ABVD, and alternating MOPP/ABVD without additive radiotherapy, revealed equal therapeutic results for ABVD and MOPP/ABVD as far as progression-free survival and OS rates were concerned. Both regimens were superior to MOPP. ABVD had less germ cell and hematopoietic stem cell toxicities. Long-term follow-up of this study demonstrated a 45% to 50% progression-free survival rate and a 65% OS rate for ABVD and MOPP/ABVD.[10]

Treatment Duration

Many groups have compared different lengths of treatment and numbers of cycles. From these studies, although the optimal duration or total dose of drugs is not known precisely, it becomes evident that at least six, but maximally eight, cycles of an anthracycline-containing drug combination appear to be sufficient.

Newer Chemotherapy Regimens

The comparable efficacy of ABVD and combinations containing alkylating agents at higher doses in recent trials indicates that cure of advanced-stage HL patients is possible without alkylating agents. However, the pulmonary toxicity of bleomycin, which is especially pronounced in children and in combination with mediastinal irradiation, remains a major problem associated with ABVD. A number of drugs showing significant responses in relapsed HL have become candidates for use in first-line therapy. The topoisomerase II inhibitor etoposide has been of special interest since promising response rates have been reported after single-agent use in refractory HL. Based on these considerations, several etoposide-containing drug regimens have been developed.

Stanford V is a seven-drug regimen, consisting of doxorubicin, vinblastine, nitrogen mustard, bleomycin, vincristine, etoposide, and prednisone. The program is applied weekly over a total of 12 weeks. Sophisticated consolidation radiotherapy to sites of initial bulky disease has been employed. In a phase II trial, 126 patients were recruited. The estimated 5-year freedom from progression rate was 89%, and the OS rate was 96% at a median observation time of 5.4 years. However, results were not reproducible and were clearly inferior in a randomized comparison with ABVD and MOPPEB-VCAD (mechlorethamine, vincristine [Oncovin], procarbazine, prednisone, epidoxirubicin, bleomycin, vinblastine, lomustine [CeeNu], melphalan, and vindesine), which in part may be explained by the use of smaller consolidating radiation fields in the randomized setting.

Dose Density and Dose Intensity

Experiences with treating several tumors in animal models have demonstrated a clear relationship between chemotherapy dose and tumor response. Retrospective analyses of drug delivery with MOPP chemotherapy showed that patients with HL who received less than the intended doses had inferior outcomes. Such dose-response relationships also were observed independently with nitrogen mustard, procarbazine, and vincristine.

Until recently, no prospective, randomized trials that analyzed the role of dose intensity in the treatment of advanced-stage HL had been conducted. In 1992, the GHSG initiated a series of clinical trials to address the role of dose intensity in advanced HL in a comprehensive way. Starting with a mathematical model of tumor growth and chemotherapy effects, the data from 705 patients with advanced-stage disease who were treated in previous GHSG studies were reassessed. The investigators predicted that moderate dose escalation would increase tumor control by 10% at 5 years. Thus the BEACOPP regimen was devised. After establishing excellent tolerability and efficacy of the regimen in a pilot trial, a second regimen of escalated BEACOPP was developed in which the doxorubicin dose was increased to a fixed level and doses of cyclophosphamide and etoposide were increased in a stepwise fashion with G-CSF support. Maximum tolerated doses were determined in a multicenter pilot study as 190% of the standard dose for cyclophosphamide and 200% for etoposide.

The GHSG then designed a three-arm study, the HD9 trial, comparing COPP/ABVD, standard BEACOPP, and escalated BEACOPP in patients with advanced HL. Radiotherapy was administered to bulky disease at diagnosis or residual disease after eight cycles of chemotherapy. About two-thirds of patients received consolidation radiotherapy. In September 1996, at the time of a planned interim analysis, the COPP/ABVD arm of this trial was closed to accrual because of superior outcomes in the BEACOPP arms. In the final analysis in June 2001, 1201 patients were evaluated. Superiority over the COPP/ABVD arm for freedom from treatment failure was observed, with 87% for escalated BEACOPP, 76% for baseline BEACOPP, and 69% for COPP/ABVD after a median of 5 years, a highly significant result. A major difference was observed in the rate of primary progressive disease during initial therapy, which was significantly lower with escalated BEACOPP (2%) than with baseline BEACOPP (8%) or COPP/ABVD (10%) (P <0.001). The OS rates were 83% for COPP/ABVD, 88% for baseline BEACOPP and 91% for escalated BEACOPP. The survival differences were highly significant (P <0.002), and the survival difference between the COPP/ABVD and the $BEACOPP_{escalated}$ regimen reached an impressive degree of significance (P <0.002). These results were confirmed and became even more significant in a 10-year update analysis of the trial published in 2009 (Fig. 74-5).[11]

As expected, escalated BEACOPP was associated with a greater degree of hematologic toxicity, including the need for a greater number of red blood cell and platelet transfusions. Second malignancies, including AML possibly related to etoposide, were reported: with escalated BEACOPP, 9 cases of AML/MDS; with baseline BEACOPP, 4 cases of AML/MDS; and with COPP/ABVD, 1 case of AML/MDS. However, the total rate of secondary neoplasias was highest in the COPP/ABVD arm, with 4.2% compared with 3.4% in the $BEACOPP_{escalated}$ arm. The death rate at 5 years, including all

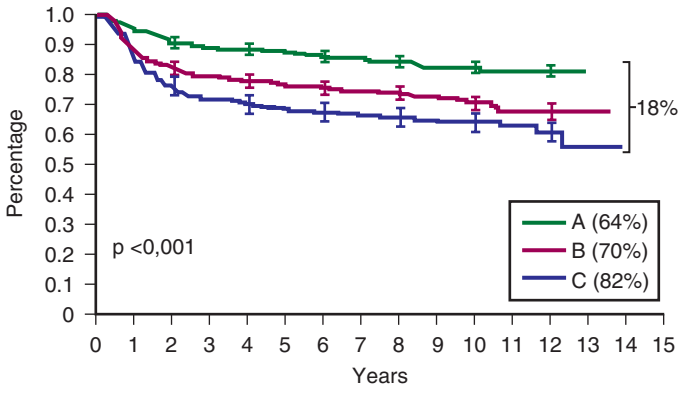

Figure 74-5 FREEDOM FROM TREATMENT FAILURE AT 10 YEARS AMONG PATIENTS TREATED WITHIN THE GHSG HD9 TRIAL FOR ADVANCED HODGKIN LYMPHOMA. **A,** COPP/ABVD. **B,** $BEACOPP_{baseline}$. **C,** $BEACOPP_{escalated}$. *From Engert A, Diehl V, Franklin J, et al: Escalated-dose BEACOPP in the treatment of patients with advanced-stage Hodgkin's lymphoma: 10 years of follow-up of the GHSG HD9 study.* J Clin Oncol *27:4548, 2009.*

acute and late causes of deaths, was 18.8% (49 of 260 patients) for the COPP/ABVD arm, 13% (61 of 469 patients) for baseline BEACOPP, and 8.6% (40 of 460 patients) for escalated BEACOPP.

Dosage, dose intensity, and total dose are decisive factors when comparing similar drug regimens. It is difficult to predict the relative efficacy of regimens that use different drugs. As mentioned above, Hasenclever proposed a theoretical framework as a first step to accomplish that task. Different drug doses in a regimen are assumed to be roughly additive in an efficacy scale when appropriately weighted. If the drug weights are known, a total chemotherapy dose can be derived. This total dose must be further corrected for different treatment durations, assuming a typical regrowth kinetic for each lymphoma entity. The resulting quantity, the effective dose, is a reasonable first-order predictor of relative treatment efficacy. Hasenclever derived drug weight estimates from a model-based metaanalysis of all randomized chemotherapy comparing trials of treatment for HL and provided an estimate of the slope of the effective dose-cure rate relationship.

Applying the effective dose model and using the weights estimated from trials up to 1998, MOPP/ABVD, MOPP/ABV, and baseline BEACOPP were predicted not to be notably different from ABVD in cure rates (all within ±5%) because their effective doses are similar. However, Stanford V was predicted to be of reduced efficacy when given with less additional radiotherapy while escalated BEACOPP was predicted to be of increased efficacy when compared with ABVD. These predictions were confirmed by the randomized trials mentioned above.

The 14-Day Variant of the BEACOPP-21 Regimen: BEACOPP-14

Increased dose intensity can be achieved by two means: increasing the dosage in the same timeframe or shortening the intervals between the treatment courses and shortening the time scale in which drugs are applied. The experiences with the highly effective but toxic $BEACOPP_{escalated}$ regimen (given in 21-day intervals) led the GHSG to consider a BEACOPP variant, in which the drug dosage and time architecture were altered according to the effective dose model of Hasenclever, with the hope of accomplishing the same efficacy but with a reduced toxicity.

The result was the development of a time-intensified $BEACOPP_{baseline}$ regimen, which was given in 14-day intervals and administered with G-CSF support for advanced-stage HL (BEACOPP-14). In a multicenter pilot study, the GHSG tested the feasibility, toxicity, and efficacy of the regimen in 99 patients in stage IIB with large mediastinal masses or extranodal disease (23%) or stage III-IV disease (77%) from July 1997 until March 2000. The final analysis with 94 evaluable patients was performed in August 2002. Ninety-one percent of patients received eight cycles of therapy; 77% were given within 16 days, and 94% were given within 22 days. Seventy percent of patients received consolidation radiotherapy. Seven patients with initial bulky disease were not irradiated. Eighty-eight patients (94%) achieved a CR, and only four patients had progressive disease. With a median follow-up of 34 months, five patients relapsed, only one developed a high-grade NHL, and three patients died, one of toxicity and two of progressive disease. The estimated rate for FFTF was 90%, and the OS rate was 97%.

Acute hematotoxicity was moderate, ranging between that of the escalated and the baseline BEACOPP regimen, with 75% of patients experiencing WHO grade 3 or 4 leukopenia. Twenty-three percent of patients experienced thrombocytopenia, and 65% had anemia, in a few cases necessitating the use of erythropoietin or blood transfusions. Since treatment results with the BEACOPP-14 regimen were promising, the regimen was thus included in the randomized HD15 trial as one comparator. Final results of this trial comparing the standard treatment consisting of eight cycles of escalated BEACOPP with six cycles of escalated BEACOPP and eight cycles of BEACOPP-14 will be available soon.

Role of Radiotherapy in Advanced-Stage Hodgkin Lymphoma

Several reports have indicated that patients treated with chemotherapy alone failed to respond or progressed, primarily in previously involved nodal sites. However, the benefits of consolidating radiotherapy must be balanced with the risk for serious side effects, particularly a second malignancy in the irradiated field.

To overcome the insufficient power of randomized studies with too few patients to detect a relevant difference, Loeffler and colleagues performed a metaanalysis of 14 studies involving more than 1700 patients. Two study designs were compared; in the additional design, irradiation was added to the same chemotherapy regimen, and in the parallel design, more cycles of chemotherapy were substituted for irradiation. In the additional design, radiotherapy reduced the hazard rate by about 40%. The benefit of irradiation was most pronounced among patients with mediastinal involvement and provided no reduction in relapse among patients with stage IV disease. There was no survival benefit detected for radiotherapy in any subgroup analyzed. In the parallel design, there was no significant difference in disease-free survival. However, OS was significantly higher among patients treated with chemotherapy alone. In the combined-modality group, there were more deaths from causes other than HL.

An important issue is determining the added efficacy of radiotherapy as adjuvant treatment to modern anthracycline-containing chemotherapy and the added late toxicity of this combined-modality treatment. Prospective, randomized trials, such as the comparison of MOPP/ABV hybrid plus or without consolidation radiotherapy by the EORTC, are needed to address these questions. In this trial, patients in complete remission after MOPP/ABV received two further chemotherapy cycles followed by randomization to involved-field radiotherapy or observation. This important study recruited patients for more than 10 years and completed the accrual with 739 patients in 2000. The final analysis published in 2003 showed that involved-field irradiation did not improve relapse-free survival or OS in patients who already achieved a CR with MOPP/ABV. Remarkably, those who reached a partial remission and were treated with additional involved-field irradiation had comparable overall outcomes compared with those who reached a CR. The added late toxicity associated with irradiation was not evaluated in this report because of the short observation time of 79 months.[12]

In the GHSG HD15 trial, patients with residual lymphoma of less than 2.5 cm after chemotherapy were not irradiated. Patients with residual lymphoma of more than 2.5 cm after chemotherapy underwent FDG-PET. Patients who were still PET-positive received consolidating localized irradiation; patients who were PET-negative were not irradiated. The negative prognostic value (NPV) of the PET examination in this situation was 94.6% so that PET-guided consolidating after adequate chemotherapy appears to be possible without an increased frequency of relapses.

Recommendations and Future Directions in Advanced Hodgkin Lymphoma

Advanced Hodgkin lymphoma has become a curable disease for the majority of patients. First-line treatment with six to eight cycles of ABVD is the widely accepted standard. However, the more aggressive $BEACOPP_{escalated}$ regimen induces a clinically relevant superior progression-free survival that translates into an improved OS in indirect comparisons. Ongoing well-designed prospectively randomized studies are currently evaluating these two approaches, and valid results will be available in the near future. In the meantime, some speculate that the early PET response-adapted design of the latest study generation will render this question redundant. Scientific interest is currently focused on these questions: (1) whether two cycles of the less-toxic ABVD regimen should be escalated to the more aggressive BEACOPP in case of PET-2 positivity, or (2) whether, after an aggressive induction therapy with two cycles of BEACOPP, further

treatment can be deescalated. Both approaches aim at finding the best balance between toxicity and efficacy for the benefit of each individual patient. Unfortunately, both approaches are not tested against each other within a single randomized trial; therefore the current debate on the standard treatment of advanced-stage Hodgkin lymphoma will very likely continue. Maybe, the future question will not be: ABVD or BEACOPP; but: do we start with BEACOPP or ABVD and switch according to the findings of an early interim PET.

PRIMARY PROGRESSIVE AND RELAPSED HODGKIN LYMPHOMA

Depending on stage and risk factor profile, up to 95% of patients with HL achieve complete remission after first-line treatment. Depending on their initial treatment, patients who relapse have different treatment options, including radiotherapy for localized disease in previously nonirradiated areas, conventional salvage chemotherapy, or HDCT followed by ASCT. Conventional chemotherapy is the treatment of choice for patients relapsing after initial radiotherapy for early-stage HL. The survival of these patients is at least equal compared with patients who initially present with advanced disease and receive chemotherapy. In contrast, patients with relapsed HL after primary chemotherapy generally have a poorer prognosis. These patients are mostly treated with HDCT with ASCT.

Newer approaches such as sequential HDCT or allogeneic SCT (aSCT) have been investigated in cases of relapsed HL. Because more aggressive approaches are associated with increased toxicity, an accurate pretreatment prognostic assessment of patients is required to help select the most appropriate therapeutic regimen.

Prognostic Factors for Patients Relapsing After Primary Radiotherapy

The relapse rate after primary radiation therapy is 30% to 35%, and most relapses occur within 3 years after completion of radiotherapy, although late relapses after 4 years have been observed in 5% to 7% of patients. This small fraction of late disease recurrence is noteworthy because this is generally a more favorable prognostic group when treated with systemic therapy. Their OS rate is not different from that of patients who never relapse.

Most patients who relapse after radiotherapy are treated with systemic combination chemotherapy, often with the inclusion of involved-field radiotherapy if an affected nodal site was previously nonirradiated. The long-term survival of patients varies significantly according to the pattern of relapse. Four major prognostic factors for response to second-line therapy include age (> 40 or 50 years), stage at relapse, duration of CR (<12 months versus >12 months) and the type of therapy used for the treatment of relapse (i.e., chemotherapy alone or chemotherapy and radiation). In some series, mixed-cellularity or lymphocyte-depleted histology were also adverse prognostic factors.

Prognostic Factors for Patients Relapsing After Primary Chemotherapy

It was first noticed in 1979 that the length of remission to first-line chemotherapy had a marked effect on the ability of patients to respond to subsequent salvage treatment. In 1992, the National Cancer Institute updated its experience with the long-term follow-up of patients who relapsed after combination-chemotherapy regimens. Derived primarily from investigations involving failures after MOPP and MOPP variants, the conclusions are relevant to other chemotherapy programs. On this basis, chemotherapy failures can be divided into three subgroups:

1. Primary progressive HL (approximately 10% of all cases) (i.e., patients who never achieved a CR or relapse less than 3 months after completion of treatment)
2. Early relapses within 12 months of complete remission (approximately 15% of all cases)
3. Late relapses after complete remission lasting longer than 12 months (approximately 15% of all cases)

Prognostic Factors for Patients With Primary Progressive Hodgkin Lymphoma

Patients with primary progressive disease, defined as progression during induction treatment or within 90 days after the end of treatment, have a poor prognosis particularly when treated with conventional salvage regimens. The 8-year overall survival rate is between 0% and 8%.

The GHSG retrospectively analyzed 206 patients with primary progressive disease to determine the outcome after salvage therapy. Rates for the 5-year freedom from second failure and OS for all patients were 17% and 26%, respectively. As reported from a number of transplantation centers, the 5-year freedom from second failure and OS rates for patients treated with HDCT were 42% and 48%, respectively, but only 33% of all patients were able to receive HDCT.

Insufficient stem cell harvests, poor performance status and older age contribute to an ineligibility to undergo HDCT. In a multivariate analysis, Karnofsky performance score at the time to progression (P <0.0001), age ($P = 0.019$), and attainment of a temporary remission to first-line chemotherapy ($P = 0.0003$) were significant prognostic factors for survival. Patients with none of these risk factors had a 5-year OS rate of 55%, compared with an OS rate of 0% for patients with all three of these unfavorable prognostic factors.[13]

HDCT is an effective treatment for a proportion of patients with primary progressive HL. Because of the poor outcomes of HL patients with progressive disease, future trials must aim at identifying patients at very high risk for induction failure and modifying primary treatment in this group to avoid progressive disease.

Prognostic Factors for Early and Late Relapsed Hodgkin Lymphoma

Many prognostic factors have been described for patients relapsing after first-line chemotherapy. These include age, gender, histology, relapse sites, stage at relapse, B symptoms, performance status and extranodal relapse. The impact of these variables is difficult to assess because of a variety of confounding factors, small numbers of patients and inclusion of patients with primary progressive HL into analyses. Multivariate analyses were not performed systematically.

Lohri and colleagues observed favorable outcomes for patients with risk factors such as an initial stage of less than stage IV at diagnosis, an absence of B symptoms at relapse, and an initial remission duration of more than 12 months. The 5-year failure-free survival rate was 82% for patients lacking all three parameters and 17% for those with one or more risk factors. Reece and associates reported an analysis of 58 patients treated with HDCT and ASCT at the same institution. Three prognostic subgroups were identified according to the presence of the following parameters at relapse: B symptoms, extranodal disease, and initial remission duration of less than 12 months. Patients with no risk factors had a 3-year progression-free survival of 100%, compared with 81% in patients with one factor, 41% in those with two factors, and 0% in patients with all three adverse risk factors. The GHSG performed the largest retrospective analysis on prognostic factors in relapsed HL published to date (n = 422). After testing several variables, the most relevant factors were combined into a prognostic score. This score was calculated on the basis of duration of first remission, stage at relapse, and presence of anemia at relapse. Early recurrence within 3 to 12 months after the completion of primary treatment, relapse with stage III or IV disease, and reduced hemoglobin levels at relapse (<10.5 g/dL for female patients, <12 g/dL for male patients) were counted in a score with possible values of 0, 1, 2, and 3, in order of worsening prognosis. This prognostic score allows the examiner to distinguish patients with

different rates of freedom from second failure and OS. The actuarial 4-year rates for freedom from second failure and OS for patients relapsing after chemotherapy with three unfavorable factors were 17% and 27%, respectively. In contrast, patients with none of the unfavorable factors had rates of freedom from second failure and OS at 4 years of 48% and 83%, respectively.

Treatment of Primary Progressive and Relapsed Hodgkin Lymphoma

Patients who relapse after achieving an initial CR can achieve a second CR with salvage treatment, including radiotherapy for localized relapse in previously nonirradiated areas, conventional salvage chemotherapy or HDCT followed by ASCT. Salvage radiotherapy alone offers an effective treatment option for a selected subset of patients with relapsed HL. This applies to patients with localized relapses in previously nonirradiated areas. In a retrospective analysis from the GHSG database including 624 relapsed or refractory HL patients, 100 patients were eligible to receive salvage radiotherapy alone: the 5-year freedom from second failure (FF2F) and OS rates were 28% and 51%, respectively. Prognostic factors for OS were B symptoms and stage at relapse, whereas performance status and duration of first remission were significant for FFTF. The survival of patients treated with conventional chemotherapy after relapse of early-stage disease is only marginally worse than that of patients with newly diagnosed advanced-stage disease. Rates of disease-free survival and OS are 52% and 67%, respectively.

The optimal treatment for recurrence after primary chemotherapy is HDCT followed by ASCT in all patients who are eligible for this treatment modality. HDCT followed by ASCT has been shown to produce long-term disease-free survival rates of 30% to 65% in patients with refractory or relapsed HL. The reduction of early transplantation-related mortality from rates of 10% to 25% reported in earlier studies to less than 5% in later studies has led to the widespread acceptance of HDCT and ASCT.

Two randomized clinical trials independently showed the superiority of HDCT followed by ASCT when compared with conventional salvage treatment. In a British trial, patients with relapsed or refractory HL were treated with a combination of BCNU (carmustine), etoposide, cytosine arabinoside, and melphalan at a conventional-dose level (mini-BEAM) or a high-dose level followed by ASCT. The actuarial 3-year rate for event-free survival was significantly better for patients who received HDCT (53% versus 10%).[14]

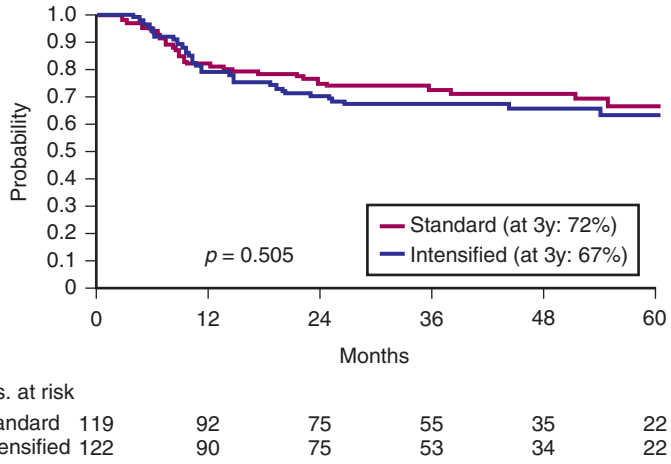
The largest randomized, multicenter trial including patients with refractory or relapsed HL was performed by the GHSG/EBMT. Patients were randomly assigned to four cycles of DexaBEAM (i.e., dexamethasone, BCNU, etoposide, cytosine arabinoside, and melphalan) or two cycles of DexaBEAM followed by HDCT (BEAM) and ABMT/ASCT. The final analysis of 144 evaluable patients revealed that among 117 patients with partial remission or CR after two cycles of chemotherapy, the FFTF rate for the HDCT group was 55% compared with 34% for the patients receiving additional two cycles of standard chemotherapy. OS did not significantly differ.[15]

Sequential High-Dose Chemotherapy

Sequential HDCT has increasingly been used in the treatment of solid tumors and hematologic and lymphoproliferative disorders. Initial results from phase I and II studies indicate that this kind of therapy offers safe and effective treatment. In accordance with the Norton-Simon hypothesis, non–cross-resistant agents are administered at short intervals after initial cytoreduction. In general, the transplantation of peripheral blood stem cells (PBSCs) and the use of growth factors allow the application of the most effective drugs at the highest possible doses at intervals of 1 to 3 weeks. Sequential HDCT enables the highest possible dosing over a minimum period of time (i.e., dose intensification).

In 1997, a multicenter phase II trial with a sequential high-dose chemotherapy program and a final myeloablative course was started to evaluate the feasibility and efficacy of this novel regimen in patients with relapsed HL. Patients between the ages of 18 and 60 years with histologically proven primary progressive HL or with first or higher grade of relapse with no prior HDCT and an ECOG performance status 0 to 1 were eligible for this study.

Treatment consisted of two cycles of DHAP (i.e., dexamethasone, cytosine arabinoside, and cisplatin [Platinol]) in the first phase to reduce tumor burden before HDCT. Patients with partial or complete remissions after DHAP received sequential HDCT consisting of cyclophosphamide (4 g/m^2), methotrexate (8 g/m^2), vincristine (1.4 mg/m^2), and etoposide (2 g/m^2). The final myeloablative course was BEAM followed by ASCT with at least 2×10^6 CD34$^+$ cells/kg.



At final analysis, 102 patients were available for the evaluation. Of those, 12 patients had experienced multiple relapses, 17 had progressive disease, 29 had early relapses, and 44 had late relapses. After a median follow-up of 30 months, results were as follows: the response rate after DHAP was 80% (72% CR, 8% partial remissions). Toxicity was tolerable, two treatment-related deaths were observed. FFTF and OS rates were 62% and 81% for patients with early relapse, 65% and 81% for patients with late relapse, 41% and 48% for patients with progressive disease, and 39% and 48%, respectively, for patients with multiple relapses.

Based on these results, the GHSG, EORTC, and EBMT initiated a prospective, randomized study to compare the effectiveness of a standard HDCT (BEAM) with a sequential HDCT after initial cytoreduction with two cycles of DHAP. Initially, 284 patients who had histologically confirmed early or late relapsed HL or who were in second relapse with no prior HDCT received two cycles of DHAP. Then 241 of these patients who had no change, partial remission, or CR after the two cycles of DHAP were centrally randomized to receive BEAM followed by ASCT or high-dose cyclophosphamide plus high-dose methotrexate/vincristine plus high-dose etoposide followed by a final myeloablative course with BEAM and ASCT. The final results of this trial were published in 2010. No significant differences in terms of treatment outcome were observed, but toxicity was increased in patients who received sequential HDCT (Fig. 74-6). Thus sequential HDCT was not adopted as standard of care in patients with relapsed HL eligible for HDCT.[16]

The Role of Nonmyeloablative Allogeneic Stem Cell Transplantation in Hodgkin Lymphoma

Given the high nonrelapse mortality of myeloablative aSCT in HL, the use of reduced intensity nonmyeloablative conditioning regimens represents a possible alternative. The goal of this strategy is to reduce the treatment-related toxicity while providing sufficient immunosuppression to facilitate donor engraftment with a subsequent graft-versus-lymphoma effect. Several published regimens exist, ranging from the truly nonmyeloablative single fraction total body irradiation with a dose of 2 Gy to moderately myelosuppressive chemotherapy-based regimens that often combine fludarabine with an alkylating agent such as melphalan or busulfan. The marked reduction of upfront toxicity with these regimens theoretically extended the applicability of aSCT to older patients, patients with comorbidities, and particularly those for whom ASCT had previously failed.

In recent years, several groups reported on the outcome of patients with relapsed HL treated with reduced-intensity conditioning and aSCT. However, these reports are often difficult to interpret because of differences in patient populations and conditioning regimens used. In general, transplant-related mortality was lower as compared with classical myeloablative conditioning regimens. A reduction in transplant-related mortality was shown by the Lymphoma Working Party of the EBMT, retrospectively comparing patients who had

Pts. at risk

Standard	119	92	75	55	35	22
Intensified	122	90	75	53	34	22

Figure 74-6 PROGRESSION-FREE SURVIVAL AMONG PATIENTS TREATED WITHIN THE HD-R2 TRIAL FOR RELAPSED HODGKIN LYMPHOMA. *Standard,* Two cycles of DHAP plus HD-BEAM plus ASCT. *Intensified,* Two cycles of DHAP plus HD-cyclophosphamide plus HD-methotrexate/vincristine plus HD-etoposide plus HD-BEAM plus ASCT. *(Josting A, Muller H, Borchmann P, et al: Dose intensity of chemotherapy in patients with relapsed Hodgkin's lymphoma,* J Clin Oncol *28:5074, 2010.)*

standard myeloablative conditioning with patients who received reduced-intensity regimens. Transplant-related mortality at 1 year was 46% in the myeloablative group and 23% in the reduced-intensity group ($p = 0.003$).[17]

There is mounting evidence that successful aSCT in HL needs a combination of an effective salvage chemotherapy and a moderately intensive pretransplant conditioning regimen to keep the disease under control and to allow the withdrawal of immunosuppression and/or the use of donor lymphocyte infusions to achieve an effective graft-versus-lymphoma response.

Another retrospective analysis by the EBMT included a total of 285 patients with relapsed or refractory HL treated with reduced intensity aSCT. The aim of the study was to identify prognostic factors predicting long-term outcome. Sixty patients died from nonrelapse mortality at a median of 91 days (ranging from 1 day to 20 months) following transplantation. The cumulative incidence estimates of nonrelapse mortality at 100 days, 1 year, and 3 years after aSCT were 10.9%, 19.5%, and 21.1%, respectively. In multivariate analysis, nonrelapse mortality was associated with poor performance status, chemorefractory disease, age of more than 45 years, and transplantation before 2002. With a median follow-up of 26 months (range 3 to 94 months), 126 patients were alive and 159 had died. The Kaplan-Meier estimates of overall and progression-free survival at 1, 2, and 3 years were 67% and 52%, 43% and 39%, and 29% and 25%, respectively. Refractory disease and poor performance status were identified as risk factors for poor overall and progression-free survival. Patients with none of these risk factors had a 3-year progression-free and overall survival of 42% and 56% compared with 8% and 25% for patients presenting with one or two risk factors. In an analysis restricted to patients who had relapsed after a prior ASCT, relapse within the first 6 months after transplant was associated with a significantly worse disease progression rate (RR = 1.9 [1.2-3.1] $p = 0.01$) and reduced progression-free survival (RR = 1.9 [1.2-2.9] $p = 0.003$) after reduced-intensity aSCT. In summary, reduced-intensity aSCT may be an effective salvage strategy for selected patients with good risk features who relapse after ASCT. The major limit of this approach, however, is the poor tumor control reported after reduced-intensity conditioning with relapse rates of 59% at 3 years. Further optimization of an aSCT approach in HL, particularly related to the optimal re-induction regimen and a better selection of patients who might benefit, is warranted.

SPECIAL CONSIDERATIONS

Nodular Lymphocyte-Predominant Hodgkin Lymphoma

NLPHL is a rare HL subtype accounting for about 5 % of all cases. Immunophenotype and the clinical course of NLPHL differ substantially from cHL. However, current standard treatment of NLPHL is not different from cHL standard treatment for most stages, a fact that can be explained by the rarity of the disease and, consequentially, a lack of clinical trials evaluating novel treatment approaches in NLPHL.

Clinical Presentation

Because of the rarity of this disease, distinct clinical features were not recognized in detail until the European Task Force on Lymphoma (ETFL) conducted an analysis comprising 219 patients with histologically confirmed NLPHL. Another analysis, in which characteristics of 394 NLPHL patients were compared with characteristics of 7904 cHL patients, was performed by the GHSG. Both analyses revealed that NLPHL was more often diagnosed in early stages. B symptoms, bulky and extranodal disease, elevation of the erythrocyte sedimentation rate and of the lactic dehydrogenase, and involvement of three or more nodal areas were less frequently found than in cHL.[18]

Treatment Results

In the GHSG analysis, FFTF (88% versus 82%) and OS (96% versus 92%) rates in NLPHL patients were superior when compared with cHL.[18] This might be due in part to the increased rate of NLPHL patients diagnosed in early stages. Patients with early favorable NLPHL in clinical stage IA have an excellent OS that is close to 100%. Different approaches can be applied in these patients. Those include watch-and-wait, radiotherapy, combined-modality strategies, and treatment with anti-CD20 antibodies.

Treatment of Early Favorable Stages

The major goal of NLPHL treatment in early stages is to induce as little acute and late toxicity as possible. Particularly in children with NLPHL, treatment strategies focus on avoiding long-term side effects such as secondary malignancies, infertility, growth retardation, hypothyroidism, and damage of heart and lung. In an attempt to postpone treatment, watch-and-wait strategies after diagnostic lymphadenectomy were evaluated in smaller series of patients. In one study including 27 pediatric patients, 13 underwent lymphadenectomy only, 10 were treated with combined-modality treatment, 1 had involved-field radiotherapy, and 3 received chemotherapy only. At a median follow-up of 70 months, OS for all 27 patients was 100% with an event-free survival rate of 69%. The event-free survival rate in the watch-and-wait group was 42% compared with 90% in those patients who had additional treatment. Patients with residual lymphoma after the diagnostic operation clearly had an inferior event-free survival when receiving no further treatment. Thus watch-and-wait must be regarded as an experimental strategy and cannot be routinely recommended in clinical practice.

For most NLPHL patients in early favorable stages, radiotherapy is the mainstay of treatment. In a smaller series including 36 stage I/IIA patients that were either treated with involved-field radiotherapy or a modified localized radiation, event-free survival and OS rates were 95% and 100%, respectively, after 5 years. A larger Australian series analyzed 202 stage I/II patients treated with radiotherapy in mantle field technique or reverted Y field. In this group of patients, the progression-free survival was 82% with an OS of 83% at a median follow-up of 15 years. In GHSG studies, a total of 131 patients with stage IA NLHPL were treated with different treatment modalities,

including extended-field radiotherapy (45 patients), involved-field radiotherapy (45 patients), and combined-modality treatment (41 patients). Median follow-up was 78 months for the extended-field radiotherapy-treated group, 17 months for those patients treated with involved-field radiotherapy, and 40 months for those who received combined-modality treatment. Overall, 99% of patients achieved a CR. There was no difference in terms of FFTF among the treatment modalities applied. Similar results were seen in a recently published large single institution retrospective study by Chen and colleagues including 113 patients with stage I or II NLPHL. In this study, outcome of patients treated with involved-field radiotherapy, extended-field radiotherapy, or combined-modality treatment was also comparable with a shorter follow-up for patients receiving involved-field radiotherapy only.[19] Although longer follow-up is required for a more comprehensive picture, the efficacy and tolerability of involved-field radiotherapy has resulted in the recommendation of this treatment modality by the GHSG for patients with stage IA NLPHL without risk factors. The EORTC has also adopted involved-field radiotherapy as standard of care for stage IA NLPHL. Similarly, the guidelines panel of the U.S. National Cancer Center Network (NCCN) recommends small-field radiotherapy as the treatment of choice for stage IA NLPHL.

In a phase II study conducted by the GHSG, 28 NLPHL patients with clinical stage IA without risk factors received four weekly doses of rituximab. The recently published final analysis showed an overall response rate of 100%. However, at a median follow-up of 43 months, 25% of patients had relapsed so that rituximab alone appears to be less effective than radiotherapy.

A North American Group conducted a trial including both patients with first diagnosis of NLPHL and relapsed disease. Patients received either four weekly doses of rituximab without further treatment (limited treatment) or four weekly doses of rituximab followed by repeated rituximab administrations every 6 months (extended treatment). Preliminary results indicate that extended administration of rituximab might prolong freedom from progression. After a median follow-up of 30 months, the median freedom from disease progression was not reached in the extended treatment group and 24 months in the limited treatment group.

Treatment of Early Unfavorable and Advanced Stages

The treatment of early unfavorable and advanced NLPHL is usually identical to the treatment of cHL. This is based on larger analyses performed by several groups that revealed similar treatment results of NLPHL and cHL patients when treated with protocols widely accepted in the treatment of HL. The GHSG analysis reported that 86% of patients in early unfavorable and 77% of patients in advanced stages reached CR. This compares with rates of 83% and 78%, respectively, in cHL patients. Only 0.3% of NLPHL patients experienced progressive disease compared with a rate of 3.9% in cHL patients. Although the overall relapse rate was very similar (NLPHL 8.1% versus 8.0% in cHL), early relapses were more frequent in patients with cHL (3.2% versus 0.8% in NLPHL), whereas late relapses were more frequent in NLPHL patients (7.4% versus 4.7% in cHL). With a median follow-up of 50 months, no significant differences between NLPHL and cHL were observed in terms of OS rates (96% in NLPHL versus 92% in cHL).[18] Similar data were reported by the ETFL. Here, at a median follow-up of 8 years, OS rate was 89% in both NLPHL and cHL.

Treatment of Relapsed NLPHL

If possible, NLPHL patients with suspected relapse should undergo a renewed biopsy since transformation into aggressive non-Hodgkin lymphoma must be excluded. In the ETFL analysis, 14% of NLPHL relapses were identified as cHL and 10% as NHL. However, patients with NLPHL showed a tendency to more favorable survival after relapse as compared with cHL patients ($p = 0.05$), but this finding must be handled with care: more NLPHL patients had been diagnosed in early stages at primary diagnosis and were treated with less intensive first-line treatment than most cHL patients.

With the advent of the anti-CD20 monoclonal antibody rituximab in the treatment of CD20-positive lymphomas, some phase II studies using this antibody were initiated in patients with relapsed or refractory NLPHL. This was based on the fact that in NLPHL not only the reactive background usually stains strongly for CD20—more important, the malignant LP cells are CD20-positive. In a study conducted by the GHSG, 14 patients were treated with weekly rituximab at a dose of 375 mg/m^2 for 4 consecutive weeks. Overall response rate was 86%. Eight patients achieved CR, and four patients partial remission. At a short median follow-up of 12 months, nine patients were in remission. An update analysis on this study including 15 patients who had reconfirmed NLPHL reported an overall response rate of 94%. With a median follow-up of 63 months, the median time to progression was 33 months; the median OS was not reached.[20] Similar results were reported from Stanford on 22 less intensively or previously untreated NLPHL patients who received rituximab. Here, response rate was 100%, but nine patients relapsed. However, with excellent response rates even in heavily pretreated patients, anti-CD20 antibodies such as rituximab and novel follow-up products might become an inherent part in future strategies for the treatment of NLPHL, possibly in combination with classical chemotherapy protocols such as ABVD or others.

Transformation into Non-Hodgkin Lymphoma

The possibility of transformation from NLPHL into aggressive non-Hodgkin lymphoma is well documented. Two recent analyses independently indicated higher transformation rates than previously reported. In one analysis including 164 patients initially diagnosed with NLPHL, the 10-year cumulative transformation rate was 12%. Another analysis including 95 NLPHL patients reported an actuarial risk for transformation to aggressive lymphoma of 7% at 10 years and of 30% at 20 years.[21]

Hodgkin Lymphoma in the Older Adult Patient

Clinical experience and data from large trials indicate that patients older than 60 years have a higher risk for treatment failure and experience more treatment-related toxicity than younger patients.[22] Regarding the incidence of HL in older adult patients, the most accurate assessments were derived from population-based studies. Two Swedish studies covering the years from 1979 to 1988 and 1973 to 1994 showed a proportion of 31% and 26% of HL patients older than 60 years, respectively. The Scotland and Newcastle Lymphoma Group (SNLG) data demonstrated that from 1979 to 2003, 624 (20%) of 3373 patients registered in the population registry were over 60 years.

The patient's physical and mental condition, disease history, and the presence of concurrent disorders influence the treatment strategy. Age in general is no contraindication against aggressive treatment, but compared with younger patients fewer older adult patients receive the intended chemotherapy dose. The survival analysis of one large comprehensive analysis performed by the GHSG showed a significantly poorer treatment outcome for older adult patients in terms of 5-year OS (65% versus 90%) and FFTF (60% versus 80%).[22] However, biologically young patients in good physical and mental condition should be treated in a stage-adapted manner.

ABVD is regarded as standard chemotherapy for most older adult HL patients. In early favorable and unfavorable stages, two to six cycles of ABVD followed by IF-RT represent a widely accepted standard of care. In advanced stages, six to eight cycles of ABVD are usually being given. However, ABVD is associated with an increased toxicity and mortality in older adult patients, so a relevant proportion of these patients might not be eligible for this regimen.

More aggressive regimens should be avoided in elderly patients since they were shown to cause unacceptable toxicity. The GHSG HD9 elderly trial was designed for patients ages 66 to 75 years in stages IIB to IV. Patients were randomized between eight cycles of COPP/ABVD (26 patients) and eight cycles of $BEACOPP_{baseline}$ (42 patients). Eighteen patients with bulky or residual disease after chemotherapy received consolidating radiotherapy. The full number of planned treatment cycles was given to 18 patients (69%) in the COPP/ABVD group and to 23 patients (55%) in the $BEACOPP_{baseline}$ group. The CR rate was the same in both treatment arms (76%), and no difference occurred regarding the number of patients with progressive disease (8% for COPP/ABVD and 7% for BEACOPP baseline). The disease-specific FFTF at 5 years was better for the more aggressive $BEACOPP_{baseline}$ regimen than for COPP/ABVD (74% versus 55%, $p = 0.13$). This did not translate into a superior OS at 5 years owing to more treatment-related fatal events in the $BEACOPP_{baseline}$ arm (21% versus 8% for COPP/ABVD).

Since etoposide was thought to contribute to the poorer tolerability of BEACOPP in older adult patients, the GHSG then developed a new BEACOPP variant especially for this patient cohort. This new schedule, BACOPP, contained no etoposide, whereas the dose of doxorubicin was increased (from 25 mg/m^2 to 50 mg/m^2). Sixty patients (92%) were eligible for the final analysis of the phase II trial evaluating the regimen. In total, 51 patients showed CR (85%), two had partial remissions (3%), and four had primary progression of disease (7%). WHO grade III to IV toxicities were documented in 52 patients (87%). With a median observation of 33 months, 18 deaths (30%) have been observed, including seven therapy-associated fatal outcomes. Thus with a therapy-associated death rate beyond 10%, this regimen also requires modification and is not recommended for routine use.

Another phase II study by the GHSG investigated the incorporation of gemcitabine into the first-line treatment of older patients. Bleomycin and dacarbazine were replaced from the ABVD backbone by gemcitabine and prednisone, resulting in the PVAG regimen. The recently performed final analysis included 59 patients with early unfavorable and advanced HL. Of these, 78% achieved a CR/CRu (complete remission unconfirmed). Three-year estimates for OS and progression-free survival were 66% and 58%.

Since HDCT followed by ASCT is not possible in most older adult patients, second-line treatment is generally of palliative nature. Several single-agents including gemcitabine and trofosphamide were described to be active in a relevant portion of patients. In addition, it may be possible to treat relapsed older adult HL patients with a second polychemotherapy—for instance, with a regimen that has been developed years ago and used by the Scottish and Newcastle Lymphoma Group (SNLG) as palliative therapy over a prolonged period. The regimen is a well-tolerated all-oral schedule consisting of prednisolone, etoposide, chlorambucil, and CCNU (PECC). Recently, an update on the use of the protocol in relapsed HL from the SNLG database demonstrated a CR rate of 58% in the 12 included patients who were older than 60 years. This finding suggests that PECC might have a useful role in the treatment of relapsed HL in older adult patients.[23] Treatment for patients with impairment of lung, liver, heart, or kidney should be adapted individually. Single drugs with organ-specific toxicities (e.g., bleomycin and doxorubicin) may be omitted, replaced, or modified in dose. Involved-field radiotherapy or the use of less aggressive drugs, such as gemcitabine and vinorelbine with or without dexamethasone are possible treatment alternatives in case standard treatment is impossible. Of note, a concomitant application of bleomycin and gemcitabine should be avoided since a high incidence of pulmonary toxicity was observed in one trial.

Hodgkin Lymphoma During Pregnancy

The peak incidence of HL occurs at female reproductive age. Therefore the association with pregnancy is not uncommon. HL is the fourth most common cancer occurring during pregnancy. One case of HL occurs per 1.000 to 6.000 deliveries. Several studies have shown that pregnancy is not associated with a worse clinical course and that the 20-year survival rate of pregnant women with HL is not different from that of nonpregnant women.

The clinical presentation of HL is not influenced by pregnancy. However, there are significant limitations regarding staging and treatment of pregnant patients. CT and PET scans should be avoided since limiting radiation exposure to the fetus is essential especially during early stages of gestation. Ultrasound is helpful for assessing the fetal status and detecting tumor lesions in the abdomen of the mother. Magnetic resonance imaging can complete the radiologic staging because it does not seem to be associated with risk to the fetus. Decisions about the need for a chest radiograph should be made on the basis of clinical examination.

In case HL is diagnosed during the first trimester, and disease requires immediate therapeutic intervention, most experts agree that a therapeutic abortion should be encouraged since the risk is high for negative effects on the development of the fetus if antineoplastic drugs are applied during that period. If an immediate start of therapy is indicated and the mother does not want to have an abortion, low-dose supradiaphragmatic irradiation or application of vinblastine monotherapy may be considered. In cases with no need for an immediate therapeutic intervention, the start of treatment should be deferred.[24]

In the second or third trimester, patients with stage I or II disease may be closely observed, and treatment can be postponed until an early delivery is achieved. If there is any sign of accelerated disease progression, especially supradiaphragmatic lymphadenopathy, radiotherapy alone is recommended. Most studies recommend doses of 10 to 36 Gy applied as mantle field or involved-field irradiation with abdominal shielding. At this time of fetal development, the risk for adverse sequelae for the child from supradiaphragmatic irradiation is low. Pregnant HL patients in the second or third trimester who present with infradiaphragmatic lymphadenopathy or advanced disease should receive combination chemotherapy. Because most chemotherapeutic agents freely cross the placenta and enter the fetal circulation, the patient and the fetus should be monitored closely. Application of cytotoxic drugs shortly before birth may be particularly hazardous because the placenta is also the primary means of drug elimination, and metabolism and excretion are delayed in the neonate. The current concept is that antimetabolites, especially methotrexate must not be given since they carry a high risk for teratogenesis, whereas doxorubicin, bleomycin, etoposide, and the vinca alkaloids appear acceptable. Thus the ABVD regimen may be used when chemotherapy is indicated beyond the first trimester. Because chemotherapeutic agents accumulate in the milk, mothers are best advised not to breast-feed during treatment.

Hodgkin Lymphoma in HIV-Positive Patients

Epidemiology and Clinical Presentation

In patients with HIV infection, HL is diagnosed more frequently than in the general population. Given the background incidence of HL in the population groups at high risk for HIV infection, researchers conducting epidemiologic studies during the first years of the HIV epidemic in North America and Europe had difficulties including HL in the spectrum of HIV-associated cancers. However, with the spread of the epidemic and longer survival of infected people, the impact of HL in HIV-positive patients could be better recognized. All studies available to date strongly support the evidence that persons infected with HIV have about a 10-fold higher risk for developing HL than do HIV-negative persons. Such an excess risk is more pronounced in HIV-infected individuals with moderate immune suppression as found in patients undergoing antiretroviral therapy. In contrast to HIV-negative patients with HL, the mixed-cellularity subtype is also more frequently found in HIV-positive HL patients and almost all cases are EBV-associated, a fact that also contrasts to what is observed in HIV-negative HL patients.

Treatment of Hodgkin Lymphoma in HIV-Positive Patients

The optimal therapy for HL in HIV-positive patients has not been defined yet. Because most patients present with advanced stages, treatment consists mainly of combination chemotherapy regimens, but the complete remission rates achieved with these regimens remain lower than in patients without HIV infection and OS is only about 1.5 years. Because of the low overall incidence of HIV-related HL, no randomized controlled trials have been conducted in this setting. After results with rather mild treatment protocols were disappointing, the widespread introduction of antiretroviral therapy allowed the use of more aggressive chemotherapeutic regimens such as Stanford V or BEACOPP. From 1997 to 2001, 59 consecutive patients were treated with Stanford V in a prospective phase II study. Treatment was well tolerated, and 69% of the patients completed therapy with no dose reduction or delay in chemotherapy administration. The most important dose-limiting side effects were bone marrow toxicity and neurotoxicity. Eighty-one percent of the patients achieved CR, and at a median follow-up of 17 months, 56% of patients were alive and disease-free. The estimated 5-year OS was 59%. Within the German group, treatment with BEACOPP in baseline dosage showed promising results in terms of CR, toxicity, and median survival. In contrast, the use of escalated BEACOPP cannot be recommended for HIV-positive patients.[25] Recently, the results of a large prospective phase II study with ABVD have been published. Within a cooperative network in Spain, 62 HIV-positive patients with HL received standard ABVD plus antiretroviral therapy. The scheduled six to eight ABVD cycles were completed in 82% of cases. Of the 62 patients, 6 died during induction, 54 (87%) achieved CR, and 2 were resistant. The 5-year overall and event-free survival probabilities were 76% and 71%, respectively. The immunologic response to antiretroviral therapy had a positive impact on overall ($p = 0.002$) and event-free survival ($p = 0.001$).

Because a large portion of HIV-positive patients with HL have progress or relapse, the use of HDCT and ASCT in this setting has been evaluated by several groups and the data published so far have demonstrated the feasibility of this approach; thus it can be considered the standard of care in progressive or relapsed patients.

SEQUELAE OF TREATMENT

Cardiac Complications

Chemotherapy-Associated Cardiac Complications

The most relevant cardiotoxic drugs used in the treatment of HL are anthracyclines. Anthracycline-associated toxicity may occur at different intervals after therapy. Cardiotoxicity often presents as electrocardiographic changes, arrhythmias, or cardiomyopathy leading to congestive heart failure. Anthracycline-associated cardiotoxicity is caused by direct damage of the myoepithelium and is strongly related to the cumulative dose applied. Doses less than 500 mg/m^2 are usually well tolerated. The total dose of anthracyclines used in the first-line therapy of HL is relatively low compared with treatment regimens used in the treatment of breast cancer or pediatric malignancies. The cumulative dose of eight cycles is 400 mg/m^2 for ABVD and 280 mg/m^2 for escalated BEACOPP. However, most patients are treated with less than eight cycles of anthracycline-containing chemotherapy.

Whether cardiac toxicity observed after chemotherapy and radiotherapy is additive or synergistic remains unclear. However, several clinical studies showed that anthracycline-containing therapy may increase the radiation-related risk for congestive heart failure and valvular disorders by two- to three-fold compared with radiotherapy alone.[26]

Radiotherapy-Associated Cardiac Complications

Radiation-associated heart disease in cancer survivors includes a wide spectrum of cardiac pathologies such as coronary artery disease, myocardial dysfunction, valvular heart disease, pericardial disease, and electrical conduction abnormalities. Radiation-associated heart diseases, except for pericarditis, usually present 10 to 15 years after exposure, although nonsymptomatic abnormalities may develop much earlier. The long delay before expression of serious damage probably explains why radiation sensitivity of the heart has previously been underestimated.

Radiation causes both increased mortality and increased morbidity. Epidemiologic studies on HL survivors show relative risk estimates for cardiac deaths in the range of two- to sevenfold higher than the general population, depending on the patient's age. An increased risk was observed for patients irradiated at young age, depending on the radiation technique used and the duration of follow-up. In a Dutch study on HL patients treated before the age of 41, standardized incidence ratios for the development of various heart diseases were three- to fivefold higher when compared with the general population, even after a follow-up of more than 20 years.[26] The persistence of an increased risk over prolonged follow-up is a major concern because this implies increasing absolute excess risks over time, based on the rising incidence of cardiovascular diseases with age.

The heart volume included in the radiation field influences the risk for cardiotoxicity, although there are still many uncertainties regarding dose- and volume-effect relationship. A reduction regarding the risk for death from cardiovascular diseases other than myocardial infarction has been reported in HL patients treated after partial shielding of the heart and restriction of the total, fractionated, mediastinal dose to less than 30 Gy. Therefore the number of radiotherapy-associated cardiac long-term sequelae might decrease in the upcoming years.

Secondary Neoplasia

Radiotherapy and certain chemotherapeutic agents such as nitrogen mustard, procarbazine, cyclophosphamide, and etoposide are well known to have the potential to induce the development of secondary malignancies.

The highest incidence of acute leukemia usually spikes within the first 10 years after initial treatment. Several analyses on incidence and outcome of secondary leukemia were performed. The largest report, which came from the GHSG, retrospectively assessed 5411 patients with HL treated within the group's studies conducted between 1981 and 1998. After a median observation time of 55 months, incidence of secondary AML/MDS was 1%. Most patients were treated with COPP/ABVD, COPP/ABVD-like combinations or BEACOPP. With a median observation of 24 months, only one patient had not died from secondary AML/MDS.[27] The classical form of a treatment-related leukemia is characterized by a latency period of 3 to 5 years, a preceding myelodysplastic phase with trilineage bone marrow dysplasia, and abnormalities of chromosome 5 and/or 7. Topoisomerase II inhibitors, especially the epipodophyllotoxins, have been implicated in the development of a clinically and cytogenetically distinct form of secondary AML. When compared with classical secondary AML induced by alkylating agents, etoposide-related AML typically occurs sooner after exposure, generally lacks a preceding myelodysplastic phase, and is characterized by balanced translocations involving chromosome bands 11q23 and 21q22.

Secondary NHL occurring after HL include intermediate- or high-grade lymphomas and present similar to lymphomas seen in patients with chronic suppression of the immune system. There is a cumulative risk of about 1.5% at 15 years for the development of these lymphomas. In general, outcome of patients with secondary NHL is worse than that of patients with primary NHL. However, some patients with secondary NHL achieve durable remission after adequate chemotherapy.

The incidence of solid tumors after HL treatment increases with time and does not reach a plateau, even in the second decade after treatment. The causative role of radiotherapy and chemotherapy is debated, but most epidemiologists tend to place greatest blame on intensive irradiation with large fields and high doses. The organs at major risk appear to be lung and breast, especially among women who were irradiated at a young age during development of the breast. A retrospective analysis by the GHSG with a median follow-up of 72 months revealed an overall cumulative risk to develop a solid secondary malignancy of 2% with relative risk estimates for secondary malignancies of lung, colon, and breast at 3.8%, 3.2%, and 1.9%, respectively. Other secondary cancers observed after successful treatment for HL include sarcomas, melanomas, and bone tumors. As indicated by registry-based reports, the portion of patients with secondary solid tumors among HL survivors will further increase with longer follow-up since radiotherapy-related secondary malignancies, in particular, have a latency of decades from exposure to the carcinogenic noxa to the diagnosis of the secondary cancer.

Gonadal Dysfunction

Of total male patients in advanced stages of HL, 78% have inadequate pretreatment semen quality as a result of the lymphoma itself. The mechanisms involved are still unknown; however, possible factors include damage of the germinal epithelium, disturbances in the hypothalamic-hypophyseal axis, immunologic processes associated with cancer that impair spermatogenesis, and the dysregulated release of cytokines. In a recent study by the GHSG, male fertility was assessed in a total of 202 patients. In pretreatment semen analyses, only 20% of patients had normal sperms. Azoospermia was observed in 11%, and other dysspermia was reported in 69% of patients.

Intensive alkylating agent–based combinations such as BEACOPP are highly gonadotoxic in males. In a recent study, posttreatment sperm analyses performed at a median of 17.4 months after completion of therapy revealed azoospermia in 64% of patients, other forms of dysspermia in 30%, and normal sperm analysis results in only 6% of cases. No statistically significant difference was found in the posttreatment status between a group of patients treated with eight cycles of $BEACOPP_{baseline}$ (with a cumulative cyclophosphamide dose of 5200 mg/m^2) and a group treated with eight cycles of $BEACOPP_{escalated}$ (with a cumulative cyclophosphamide dose of 10.000 mg/m^2). In contrast, ABVD, probably the most widely used regimen in the treatment of HL, is less gonadotoxic, with gonadal damage that might be only transient. However, because of the gonadotoxic effects of many drugs used in the current treatment of HL, cryoconservation should be offered to every young male before starting with chemotherapy.

Gonadal complications affect female patients as well. As with males, alkylating agents are most commonly involved in treatment-associated gonadal damage in female patients. In a retrospective analysis by the GHSG, the menstrual status after HL treatment of 405 female patients younger than 40 years was analyzed. With a median follow-up of 3.2 years, 51.4% of women who had received eight cycles of escalated BEACOPP had continuous amenorrhea. Amenorrhea was significantly less common in women treated with two cycles of ABVD (3.9%), two cycles of alternating COPP/ABVD (6.9%), four cycles of alternating COPP/ABVD (37.5%), or eight cycles of BEACOPP baseline (22.6%). In a multivariate analysis, amenorrhea was most pronounced in women with advanced-stage HL, women older than 30 years of age at treatment, and women who did not take oral contraceptives during chemotherapy.[28] After ABVD alone, chemotherapy-induced ovarian failure is less likely, especially when women are younger than 30 years at the time of treatment. Older women have a significantly lower likelihood of ovarian recovery than those of younger age. In the GHSG analysis, 40% of women younger than 30 years of age experienced amenorrhea after treatment with eight cycles of escalated BEACOPP, compared with 70% of women aged 30 or older.

Quality of Life

A review of most randomized clinical trials in HL reveals that quality of life (QOL) has been neglected as primary or even secondary outcome measure in the past. However, the number of clinical trials evaluating health-related QOL (HRQOL) is increasing. It has become widely accepted that the multidimensional approach of HRQOL assessment reflects the patient's situation and reveals important information for the process of treatment evaluation. With the constantly growing cohort of long-term survivors indicating the progress of cancer therapy, new approaches in HRQOL assessment are needed in order to deal with the particular problems of these long-term survivors. Several studies have highlighted the difficulties that survivors may experience long after treatment ends, such as general fatigue, health fragility, and social and financial problems. These findings have been demonstrated in studies in which an HRQOL approach has been used. Since most of these studies used a cross-sectional design, the need exists for new approaches to describe patient situations more precisely, to detect reasons for maladaptation, and to identify patients at high risk for developing problems.

Combined comprehensive approaches could help to overcome the difficulties in assessing HRQOL in long-term survivors. Furthermore, this approach can be used with few modifications in the assessment of normal control persons. It seems plausible that many years after treatment, daily living circumstances have a stronger impact on a patient's HRQOL. Therefore it is essential to also have reference data from age- and gender-matched healthy persons for the interpretation of HRQOL results. In addition, a more comprehensive approach that accounts for each patient's life situation is necessary to represent the complexity of HRQOL. Results from studies by the EORTC/GELA and the GHSG within the next few years should reveal whether this approach is successful. Quality-of-life assessment should benefit patients by defining relevant issues, even long after initial treatment. Well-designed prospective studies must evaluate disease- and therapy-independent predisposing factors for long-term HRQOL functions as well as those factors associated with the applied therapy or the lymphoma itself.

NEW DRUGS IN HODGKIN LYMPHOMA

Despite the excellent cure rates achieved with current first-line protocols, treatment of relapsed or refractory HL has remained a field o f unmet medical need. Relapse after HDCT and ASCT, in particular, is associated with poor prognosis and a median OS of less than 3 years. This section provides a brief introduction to some of the new drugs being used in HL treatment, including monoclonal antibodies, immunotoxins, radioimmunoconjugates, and small molecules.

Anti-CD30 Antibody-Based Approaches

Because it is selectively overexpressed on HRS cells, CD30 is considered a privileged target antigen for antibody-based immunotherapy of cHL. However, despite encouraging preclinical data, results of phase I/II clinical trials with naked first-generation anti-CD30 antibodies were disappointing. Both first-generation antibodies applied in HL patients, MDX-060 and SGN-30, showed only modest clinical activity when given as single agent. In a phase I/II trial, a total of 72 patients with CD30-positive malignancies, including 63 patients with multiple relapsed HL, were treated with MDX-060, but only 6 patients achieved an objective response and only 25 had stable disease. In another phase II trial using a different monoclonal antibody (SGN-30), none of the 38 HL patients responded. Several possible reasons may explain this lack of activity, including poor binding properties in vivo and a neutralization of the antibodies by the soluble form of CD30 shed from the target cells.

The most advanced and promising anti-CD30 construct so far is the antibody-drug conjugate SGN-35 (brentuximab vedotin) consisting of the antibody cAC10 and the synthetic antimitotic agent monomethylauristatin. In a phase 1 trial, 42 patients with relapsed HL, 2 patients with systemic anaplastic large cell lymphoma, and 1 patient with angioimmunoblastic T-cell lymphoma were included. With a median of three prior lines of treatment, 86% of patients showed reductions in target lesion size. Side effects were mainly mild and manageable.[29] A pivotal phase II trial including 102 HL patients with relapse after HDCT and ASCT finished recruitment at the end of 2009.

Antibody-Based Strategies Targeting Other Antigens

CD25 (interleukin-2 receptor) is expressed on a few normal cells and can consistently be found on malignant cells in a number of lymphoma entities, including HL. Therefore a rationale follows to target CD25 with antibodies and antibody-based constructs. Efficacy and safety of a radioimmunoconjugate consisting of an anti-CD25 antibody (daclizumab) and radioactive yttrium-90 (daclizumab-90Y) were evaluated in a phase II trial including 30 heavily pretreated HL patients (1 to 8 prior lines of treatment). Response rate was promising, with 19 patients achieving either partial (7 patients) or complete (12 patients) remission. Only six patients showed disease progression. However, because the drug also exhibited relevant toxicity, with seven patients showing an insufficient platelet count recovery and three patients developing MDS, the future role for this treatment approach is unclear despite its clearly proven antilymphoma activity.

Small Molecules

An increasing number of small molecules have become available in recent years. As examples of this group of drug, the immunomodulatory drug lenalidomide, the histone deacetylase inhibitor panobinostat, and the mTOR inhibitor everolimus will be described in this section.

The efficacy of the thalidomide-derivate lenalidomide has been independently reported by different groups as a single-agent treatment in HL patients who had relapsed after ASCT. In an individual patient program conducted by the GHSG, 12 patients with a median of six prior therapies received lenalidomide at doses of 25 mg/day for 21 days of each 28-day cycle. Of these patients, 50% responded to treatment. Hematologic and nonhematologic side effects were mostly mild and manageable and did not prevent continuation of treatment at the initial dose level.[30]

An interim analysis of a phase II trial using the same treatment schedule reported the outcome of 15 patients with relapsed disease, 13 of whom had not responded to their prior treatment. Partial remission or CR was achieved by 33% of evaluable patients, and another 25% had stable disease lasting 6 months or longer. In this trial, treatment was also well tolerated; thus lenalidomide appears to be active in a relevant portion of heavily pretreated patients without excessive or treatment-limiting toxicity. Therefore lenalidomide can also be considered as a possible part of combination therapies with other small molecules, antibodies, or conventional chemotherapy.

Histone deacetylases are a family of enzymes involved in diverse activities, including cell proliferation, survival, angiogenesis, and immunity. In recent years, several histone deacetylase inhibitors were developed for clinical use, including vorinostat, MGCD0103, and panobinostat. Larger trials have already finished recruitment, but no final analyses are available to date.

The PI3K/Akt/mTOR pathway is aberrantly activated in many cancer entities. This pathway was also shown to be dysregulated in HRS cells by several mechanisms, including activation of CD30 and CD40; thus it is considered a possible target pathway for novel treatment approaches. Safety and activity of the mTOR inhibitor everolimus were proven in a phase II study including 19 patients who continuously received 10 mg of the drug. Of these patients, 47% responded to treatment, with eight patients achieving partial remission and one achieving a complete remission. No excessive toxicity was observed. Thus the drug is currently undergoing further clinical studies.

CHAPTER 75

ORIGIN OF NON-HODGKIN LYMPHOMA

Matthew S. McKinney and Sandeep S. Dave

Over the past 2 decades, discoveries in basic immunology and the pathogenesis of malignancies have significantly advanced our understanding of the origin of lymphoid neoplasms. These diseases have been reexamined and grouped based on recurrent chromosomal rearrangements, histologic patterns, and gene expression profiles. The multiple revisions to the World Health Organization's classification schemes for lymphomas reflect this progress. As with other cancers, acquisition of sequential mutations and recurrent chromosomal rearrangements involving oncogenic pathways as transformation events characterize B-cell lymphomas. Many of these derangements occur as a result of disordered genetic recombination and somatic hypermutation events intended to support adaptive immunity.

An evolving understanding of the steps involved in normal B-cell development has provided further insights into the development of this diverse group of malignancies because most non-Hodgkin lymphomas (NHLs) reflect stages of B-cell development. The application of gene expression profiling (GEP) and massively parallel high-throughput sequencing, as well as a better appreciation of the contribution of microRNAs (miRNAs) and epigenetic alterations to lymphoma pathogenesis, have shed new light on the mechanisms underlying lymphomagenesis. Correlation of these findings with the clinical outcomes has further refined prediction of outcome and has suggested targets for novel therapies.

This chapter reviews the most common B-cell NHLs with regard to classification using prevailing views regarding genetic or genomic classification of these disorders. Additionally, insights regarding pathogenesis, prognosis, and possible therapeutic targets gleaned from genomic approaches are discussed.

OVERVIEW OF B-CELL LYMPHOMAS

B-cell lymphomas often represent immortalized, "frozen" stages of B-cell development. The goal of early B-cell development is to produce mature B cells expressing surface immunoglobulin M (IgM) that can efficiently recognize cognate antigen. After this is accomplished, B cells develop along pathways involving germinal center (GC), mantle, and marginal zones in lymphoid organs where they encounter antigen in association with activated antigen-presenting cells (APCs). Differentiation of mature B cells into plasma cells after somatic hypermutation is the final step in B-cell development and is critical to the development of effective humoral immunity. Antibody diversity is accomplished through the process of somatic V(D)J recombination at the pro–B cell stage via recombinase activating genes (*RAG1* and *RAG2*) followed by trafficking to GCs, where they proliferate rapidly with dividing times of 6 to 8 hours. High-affinity B-cell clones produced in part via activation-induced cytidine deaminase (AID) expression and somatic hypermutation (SHM) are favored because of protection from apoptosis. Through this mechanism, protective antibodies are produced at the risk of exposing antigen-stimulated B cells to genetic lesions caused by the molecular machinery utilized to create V(D)J recombination and SHM. Many NHLs exhibit translocations of driver oncogenes to highly active Ig loci, implying that recombination events intended to produce high-affinity antibodies are misdirected and instead produce immortalized B cells representing stages of B-cell development. Furthermore, mutations in oncogenes or tumor suppressors frequently occur in a pattern consistent with SHM at these loci. When considered together with the recurrent chromosomal rearrangements noted in NHL, this confirms the notion that these neoplasms stem from mature B cells that have entered (or are poised to enter) GCs.

Subsets of NHL recapitulate this pattern of normal B-cell differentiation at the histologic, molecular, and genomic levels and serve as a template for the classification of these diseases. This template can be applied to the entire spectrum of B-cell neoplasms as outlined in Fig. 75-1, suggesting that NHLs form as a result of genetic alterations developed along this process. B-cell differentiation must be carefully choreographed at the molecular and genomic level because the expression of the *RAG* genes and AID cause DNA strand breaks and put the nascent lymphocyte at risk of oncogene overexpression and tumor suppressor deletion. Moreover, a coordinated regulation of gene expression is required to allow such genomic revision without triggering reflexive, protective apoptotic pathways and to allow appropriate B-cell differentiation. GC B cells highly express BCL6, and its functions are critically important to regulation of cell survival and differentiation. Targets of BCL6 also include cell cycle regulators (p21, p27) and TP53, which may overall work to facilitate cell cycle progression in the face of ongoing AID-mediated DNA strand breaks. BCL6 also represses *PRDM1*/Blimp1 and serves to prevent plasmacytic differentiation. Plasma cell differentiation is mediated by upregulation of IRF4 and nuclear factor kappa-B (NFκB), which establish characteristic regulatory programs.

Genetic lesions altering these pathways are found recurrently in NHL. *BCL6* rearrangements occur in diffuse large B-cell lymphoma (DLBCL) and other lymphomas, and constitutively active NFκB signaling is associated specifically with aggressive phenotypes of DLBCL. Translocations of *BCL2,* which is expressed at very low levels in GCs, occur in almost all follicular lymphomas (FLs) and illustrate the dangers of aberrant recombination events in the GCs because *BCL2* translocation appears to be a primary event in the formation of these tumors.

Recent work has also suggested a role for miRNAs in B-cell development. Multiple miRNAs are required at various steps across B-cell development, and patterns of miRNA expression can be correlated to individual stages of B-cell maturation. In particular, miR-150 and mi17~92 clusters downregulate pre–B cell development, and miR-155 has been implicated in disordered humoral immunity and the development of NHL. Interestingly, mi17~92 appears to drive oncogenic mTOR (mammalian target of rapamycin) signaling in GC origin DLBCLs as well. Important regulators of germinal center B (GCB) transition, including LMO2 and Blimp1, appear to be regulated by miRNAs, and maintenance of this phenotype may play a role in NHL formation. Interestingly, miRNA profiles in NHL also reflect their cell of origin, highlighting their importance in maintaining the B-cell phenotype.

Antigen stimulation of the B-cell receptor (BCR) is important in both B-cell maturation and the development of NHL. The BCR consists of a multimeric signaling complex, including CD79A and CD79B, which acts through the immunoreceptor tyrosine activation motif on CD79B and leads to a cascade of molecular events involving SYK and BTK signaling. The end-result of this cascade is an increase in cellular proliferation through activation of NFκB target genes and

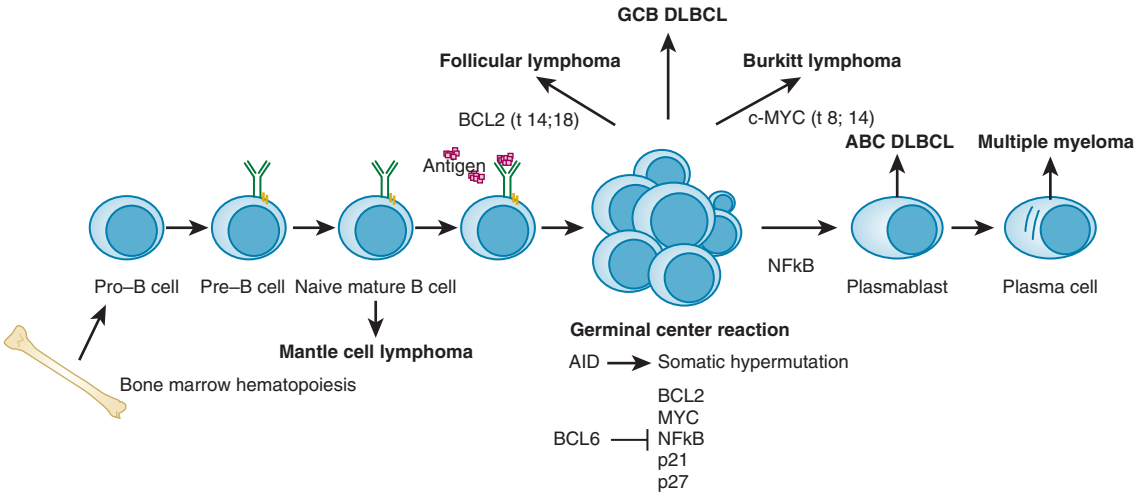

Figure 75-1 CLASSIFICATION OF COMMON NON-HODGKIN LYMPHOMAS (NHLs) IN RELATION TO B-CELL DEVELOPMENT IN GERMINAL CENTERS (GCs). Hematopoiesis results in B-cell precursors that ultimately produce immunoglobulin M (IgM) that recognize cognate antigen via activation of recombinase activating genes (*RAG1* and *RAG2*) and a GC reaction occurs. A regulatory program relying on BCL6 regulation of cell proliferation and apoptosis occurs at this point, and rearrangements presumed to occur along this course result in post-GC lymphomas, including follicular lymphoma, Burkitt lymphoma, and diffuse large B-cell lymphoma (DLBCL). The underlying molecular biology of NHL subsets (and other lymphoid neoplasms) reflects the GC step and other stages of B-cell development. For example, gene profiling of DLBCL reveals that whereas activated B cell–like (ABC) DLBCL reflects the plasmablast stage along normal B-cell development, multiple myeloma expressesion profiles more consistent with differentiated plasma cell origin.

other cellular machinery. Almost all NHLs express surface Ig, suggesting that functional BCR signaling is important at some point in the process of lymphoma formation. Analysis of Ig SHM patterns in lymphoma samples further suggests that antigen-induced selective pressure is important in the pathogenesis of NHL. The antigen(s) involved in this process are unknown, and it is also unclear whether ongoing antigen stimulation is important in subsets of NHL.

Epidemiologic studies have bolstered the argument that chronic immune activation and inflammation are connected with NHL development; these data also suggest that immune surveillance plays a role in the origin of NHL. DLBCL and Burkitt lymphoma (BL) occur more frequently in immunocompromised hosts and are often Epstein-Barr virus (EBV) positive. HIV/AIDS is a significant risk factor for post-GC neoplasms, and this risk is attenuated with the use of highly active antiretroviral therapy. For example, the risk of central nervous system lymphomas is increased more than 1000-fold in patients with AIDS. NHL also occurs more frequently in acquired or inherited immunodeficiencies such as common variable immunodeficiency and severe combined immunodeficiency and with solid organ and hemopoietic transplantation. Situations in which chronic infection or inflammation occurs have also been linked to NHL. Gastric MALT *(Helicobacter pylori),* hepatosplenic T-cell lymphoma (associated with infliximab use), and thyroid NHL (Hashimoto thyroiditis) are specific instances in which the development of lymphoid malignancy can be traced to chronic inflammation, either of microbial or autoimmune etiology. A critical association with EBV has been noted for NHL and is most frequently seen in posttransplant lymphoproliferative disorder, a disease that occurs in the setting of organ transplantation and immunosuppression targeting cellular immunity.

Beyond these factors, the contributions of modifiable risk factors and heredity appear to play only a small role in NHL development. Any increased risk contributed by inherited genetic factors appears to be almost negligible. Furthermore, several environmental factors (pesticides, Agent Orange, radiation exposure) have been implicated in NHL, but the associations between these agents and lymphomagenesis are difficult to prove. Pesticide exposure does appear to have a dose-effect relationship with regard to NHL pathogenesis and has been linked to recurrent t(14;18) cytogenetic rearrangements that are noted in DLBCL and FL.

Together, these observations reinforce the notion that NHLs originate from disordered lymphoid development. Factors related to immune surveillance, lymphoid proliferation, or Ig gene rearrangement appear to be the most important factors for the development of NHL.

DIFFUSE LARGE B-CELL LYMPHOMA

Diffuse large B-cell lymphoma is the most common subtype of NHL (≈25% of all NHL) and is responsible for more patient deaths than any other form of lymphoma. This entity often presents at an advanced stage, and around 50% of all patients fail to respond long-term to standard chemotherapy programs; the vast majority of those patients will eventually succumb to their disease. Even prior to the availability of gene expression profiling technology. It was clear clinically (based on tumor morphology, immunohistochemical staining, and patient outcomes) that DLBCL is a heterogeneous disease. Advances in molecular biology and genomic technologies have clarified the basis for some of this observed heterogeneity, and it has become clear that DLBCL comprises a diverse group of lymphomas that have distinct cellular origins, recurrent gene mutations, and chromosomal rearrangements that dictate their behavior. It is also clear that the stromal environment appears to play a key role in the development and progression of DLBCL, as with other cancers.

GENE EXPRESSION PROFILES DEFINE DIFFUSE LARGE B-CELL LYMPHOMA SUBTYPES (Table 75-1)

Gene expression profiling has identified GCB and activated B cell–like (ABC) DLBCL subsets that express gene signatures that mimic GCs and activated B cells (Figs. 75-2 and 75-3). Roughly 30% of DLBCLs cannot be classified using this system and have been deemed unclassified DLBCL. There are thousands of genes that differ between these subtypes at the GEP level, which is a magnitude similar to that seen between acute myeloid and lymphoblastic leukemias, which have profoundly different mechanisms of origin and natural histories.

Germinal center B DLBCLs express a characteristic spectrum of genes and have ongoing AID-mediated somatic hypermutation as

Table 75-1 Frequency of Recurrent Genetic Aberrations in Diffuse Large B-Cell Lymphoma Subtypes

Rearrangement, Amplification, or Deletion	ABC DLBCL	GCB DLBCL	PMBL	Notes
BCL2 translocation t(14;18)	0%	40%-50%	20%	Alternatively translocated to light chain loci 5%-10% of time
BCL2 amplification	34%	10%	16%	
BCL6 translocation t(3;V)(q27;V)	25%	10%	20%	Variable translocation partners (14q32, 2p11, 22q11, 4p11, 6p21, 11q23)
3q amplification	25%	0%	<5%	
9q24 amplification	5%	0%	45%	
PRDM1/PRDM1 deletion/mutation	25%	0%	Unknown	
REL amplification	0	15%	25%	
MYC rearrangement t(8;14)(q24;q32)	5%-10% of all DLBCLs			25%-30% occur with t(14;18)(q32;q21)
TP53 deletion	Mutations, deletions, or both in 20% of DLBCLs

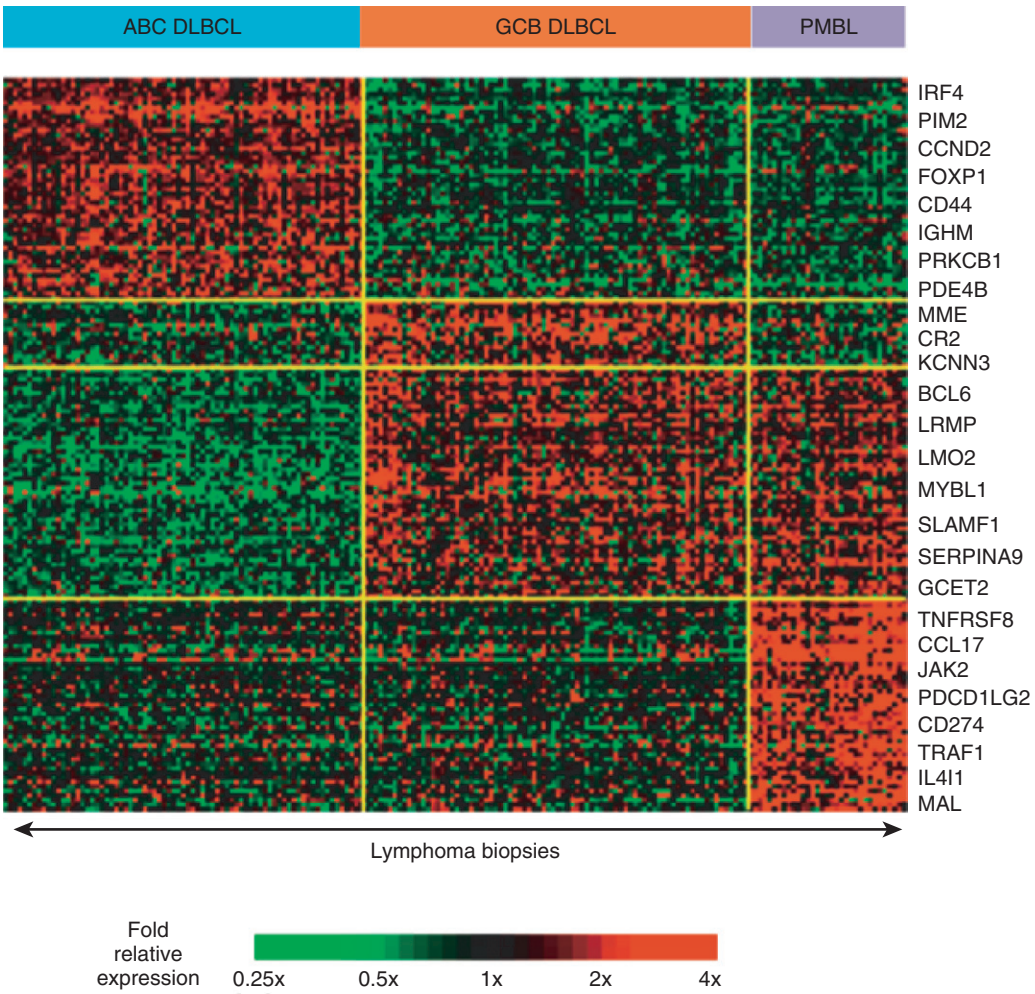

Figure 75-2 GENES CHARACTERISTICALLY EXPRESSED BY SUBGROUPS OF DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL). Activated B-cell–like (ABC) DLBCL, germinal center B cell–like (GCB) DLBCL, and primary mediastinal B-cell lymphoma (PMBL). Each column represents gene expression data from a single DLBCL biopsy sample, and each row represents expression of a single gene. Relative gene expression is indicated according to the color scale shown. *(See Alizadeh, AA: Distinct types of diffuse large B-cell lymphoma identified by gene expression profiling.* Nature *403:503, 2000.)*

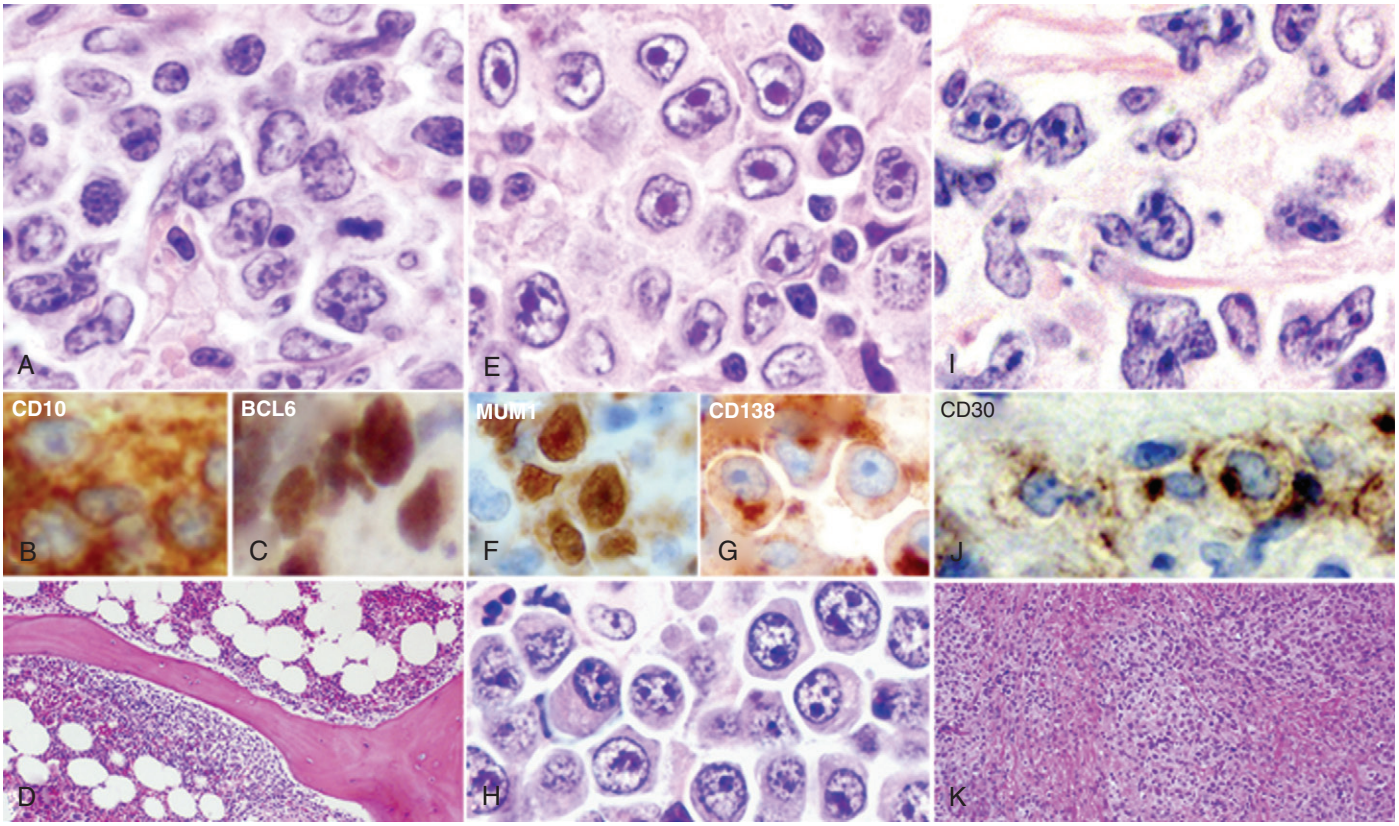

Figure 75-3 THREE TYPES OF DIFFUSE LARGE B-CELL LYMPHOMA DELINEATED BY HISTOLOGIC PATTERNS. Germinal center B cell–like (GCB), activated B-cell–type, and primary mediastinal B-cell lymphoma (PMBCL) type. GCB, or germinal center (GC)–derived large B-cell lymphomas usually have a centroblastic morphology **(A),** are $CD20^+$, and express the GC markers CD10 **(B)** and BCL6 **(C).** In this case, the patient's staging bone marrow **(D)** showed paratrabecular involvement by small cleaved cells (centrocytes), indicating that the large B-cell lymphoma likely arose from a lower grade follicular lymphoma. Activated B cell–like large B-cell lymphoma can sometime have an immunoblastic morphology **(E)** and can typically express MUM1 **(F)** and CD138 **(G).** These post-GC cell types of lymphomas can also have a plasmablastic morphology **(H),** as sometimes seen in HIV-related cases. PMBCLs are frequently composed of multilobated centroblasts **(I).** They are typically $CD45^+$, $CD20^+$, and usually $CD30^+$ **(J)** but CD15 negative. Surface immunoglobulin may be negative on such cases. PMBL is commonly associated with fibrosis, which is present in broad bands **(K)** or surrounding individual cells (as in **I**).

well as a histologic phenotype consistent with GC origin. BCL6 and LMO2 are both important to the transcriptional program of GCs and are commensurately overexpressed in GCB DLBCLs. Conversely, *PRDM1* is downregulated by BCL6, which results in decreased *PRDM1* activity in GCs, and GCB DLBCLs display a similar pattern. Histologically, GCB DLBCLs are characterized by CD10 expression and lack of IRF4 expression. Evaluation of Ig loci within GCB DLBCLs has also revealed evidence of ongoing SHM, which is further evidence that GCB DLBCLs reflect the biology of normal GC B cells and that dysregulation of pathways involved in GC formation might lead to this subset of DLBCL.

Alternatively, the ABC subtype of DLBCL expresses a post-GC phenotype but appears trapped just before differentiation into plasma cells. ABC DLBCLs are characterized by downregulation of many GC genes, including *BCL6* and *LMO2,* and by expression of genes associated with activated B cells and plasma cells. One of the hallmarks of the ABC DLBCL phenotype is upregulation of NFκB. NFκB is a transcription factor that targets a number of gene programs governing cell proliferation, immortality, and angiogenesis within NHLs. The effectors of NFκB signaling exist in inactive form in the cytosol and require signaling either through MAPK/ERK (mitogen-activated protein kinase/extracellular signal-regulated kinase) signaling (the canonical NFκB pathway) or through ligation of CD40–LTbR–BAFF-R (B-cell activating factor receptor), which results in phosphorylation of the inactive complex and translocation of either the p50–RelA or p52–Rel B complexes to the nucleus and subsequent transcription of target genes. In ABC DLBCL cell lines, a signaling complex involving CARD11, BCL10, and MALT1 (the CBM complex) constitutively activates NFκB signaling and selective knock-down of any of the components of this complex using RNAi or small molecule inhibitors and is lethal to ABC cell lines. Interestingly, a few GCB cell lines also demonstrate activation of NFκB and mutations in the NFκB pathway, which might confer sensitivity to inhibition of this pathway in those tumors. The mechanisms by which DLBCLs acquire and maintain constitutive NFκB activity are still being elucidated and may provide insights into the origin and into possible treatments for this entity.

Primary mediastinal B-cell lymphoma (PMBL) represents a distinct subset of patients that have sometimes been classified as DLBCL. PMBL was originally identified based on the clinical characteristics of the disease. Patients with PMBL are generally young (third or fourth decades of life), predominantly women, and present with a large mediastinal mass; outcomes with chemoimmunotherapy for PMBL are generally superior to those with other subtypes of DLBCL. GEP studies revealed that PMBL could be clearly delineated from ABC and GCB, subtypes. Indeed, by gene expression, PMBL appears similar to Hodgkin lymphoma with many shared features in both diseases, including the expression of CD30. Both diseases also express genes associated with JAK (Janus-activated kinase)–STAT (signal transducer and activator of transcription) signaling as well as targets of the NFκB pathway.

Molecular Pathogenesis of Diffuse Large B-Cell Lymphoma

Investigation of the molecular landscape of DLBCL has revealed a set of recurrent cytogenetic and molecular abnormalities associated

with pathogenesis. Chromosomal translocations involving *BCL6, BCL2,* and *MYC* (v-*myc* myelocytomatosis viral oncogene homolog) occur frequently in DLBCL, and these translocations appear to reflect cell-of-origin phenotype. 3q27 rearrangement with Ig gene partners is the most common rearrangement seen in DLBCL and occurs in about 30% of both the ABC and GCB subtypes. This genetic rearrangement upregulates the *BCL6* gene, resulting in an oncogenic phenotype. Additional mutations in the transcriptional regulatory program of *BCL6* may also occur with alternative translocation. Notably, *BCL6* translocations appear to not be sufficient for lymphoma formation as evidenced by mice bearing t(3;14) translocations that develop NHL at a low rate. *BCL2* translocations occur in a minority of GCB DLBCLs but are not seen in the ABC phenotype; this mirrors the situation in FL, in which *BCL2* overexpression results in disordered GC transit. *MYC* rearrangements additionally occur in DLBCL (≈5% of cases), sometimes with rearrangements of *BCL2, BCL6,* or both. These tumors, sometimes termed *double-hit lymphomas,* display an aggressive phenotype seemingly intermediate between BL and DLBCL.

Oncogenic mutations and areas of chromosomal amplification or deletion also appear important in the pathogenesis of DLBCL. Upregulation of c-REL occurs in about 20% of GCB tumors through amplification of the 2p locus. Amplification of *MYC* and *BCL2* may also occur through this mechanism. *TP53* mutations and SHM of other loci, including *PIM1, BCL6,* and *MYC,* also appear to contribute to lymphoma formation and progression. Mutations in *CARD11* causing constitutive NFκB activation have been described in a subset of both ABC and GCB DLBCLs and appear to drive oncogenesis in these tumors. Overall, the patterns of gene mutation and recurrent cytogenetic abnormalities add further complexity to the classification of DLBCLs.

Recurrent mutations of genes involved in DLBCL pathogenesis have also been reported. Inactivating mutations of *PRDM1* and mutation in genes regulating NFκB signaling *(TNFAIP3, MYD88, CARD11)* have been noted in ABC DLBCL subtypes. *CD79B* and *BCL2* have also been found to harbor mutations in DLBCL and other NHLs. Most recently, several groups have reported analyses of whole-genome, exome, or transcriptome data from the application of massively parallel sequencing in DLBCLs. These studies identified novel mutations in genes that play roles in histone modification as well as a number of other processes in DLBCLs. A series that performed RNA sequencing on 127 NHL samples (including 83 DLBCL tumors) found 651 coding single nucleotide variants (cSNVs), many of which were not previously documented in malignancies. Truncating deletions in tumor suppression genes *(TP53, TNFRSF14, CREBBP)* were among the most significantly mutated genes and other heavily mutated genes not previously known to be involved in DLBCL pathogenesis (including *MLL2, BTG1,* and *GNA13*). *MLL2* contained cSNVs in 26% of tumors and most often occurred as a heterozygous defect, and sometimes multiple mutations occurred in trans MLL2 functions as a H3K4-specific methyltransferase responsible for regulation of transcription of developmental genes. Ostensibly, MLL2 might serve to deregulate genes involved in differentiation or development and act in conjunction with other oncogenes to facilitate NHL. Other groups have confirmed mutations in *MLL2* and other genes *(CREBBP/EP300)* that coordinate chromatin acetylation, leading to the hypothesis that mutations in histone-modifying genes lead to DLBCL and other NHLs. Further work is needed to understand how these genetic lesions may be targeted for DLBCL treatment.

The Tumor Microenvironment and Diffuse Large B-Cell Lymphoma

The complexities of antigen presentation and recognition and regulation of B-cell proliferation that occur in GCs suggest that the microenvironment may play a role in the origin and progression of DLBCL. Tumor-infiltrating T cells have been correlated to longer survival in patients with DLBCL, and failure of immune editing is likely responsible for the increase in NHL in HIV-positive and immunosuppressed persons. GEP has been used to define stromal elements related to DLBCL progression. In one series, hierarchical clustering was used to define three groups among DLBCL samples by GEP. Clusters identifying gene signature termed *oxidative phosphorylation, BCR proliferation,* and *host response* were identified; notably, the host response group exhibited gene expression profiles associated with T and natural killer cells, dendritic cells, and macrophages. This work illustrates that patterns of stromal involvement in DLBCL could play a key role in pathogenesis. In another series involving biopsy specimens from 414 patients treated with chemotherapy and immunochemotherapy, two gene signatures characterizing patterns of tumor stroma best predicted survival (Figs. 75-4 and 75-5). Improved survival was noted with a pattern that included genes associated with the extracellular matrix and histiocytic infiltration. The converse was true for gene profiles correlating to angiogenesis because these were associated with far worse overall survival.

Although it is not known what roles distinct lymph node subsets play in the pathogenesis of lymphoma, it is clear from these studies that the tumor microenvironment plays a role in the origin of NHL.

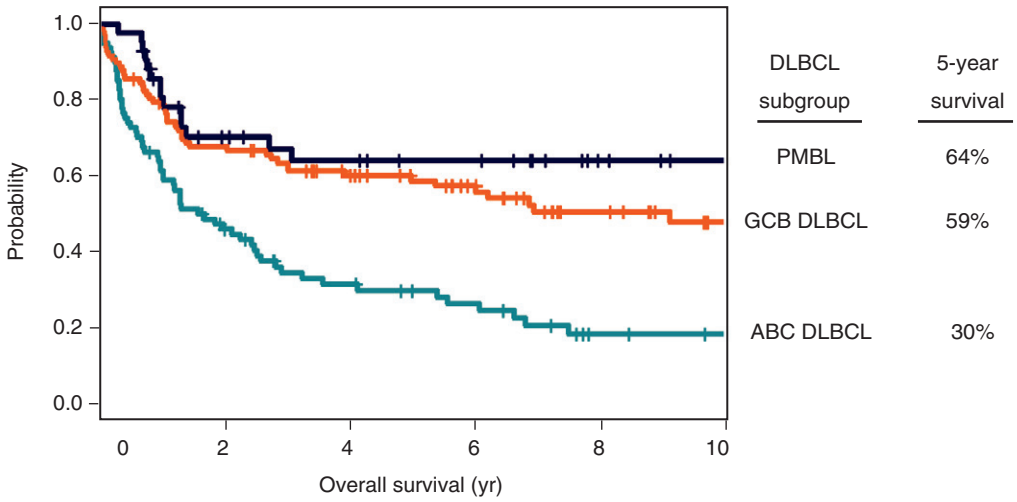

Figure 75-4 KAPLAN-MEIER PLOT OF OVERALL SURVIVAL FOR DIFFERENT DIFFUSE LARGE B-CELL LYMPHOMA SUBGROUPS TREATED WITH ANTHRACYCLINE-CONTAINING CHEMOTHERAPEUTIC REGIMENS. *(From Rosenwald, A: The use of molecular profiling to predict survival after chemotherapy for diffuse large-B-cell lymphoma.* N Engl J Med *346:1937, 2002.)*

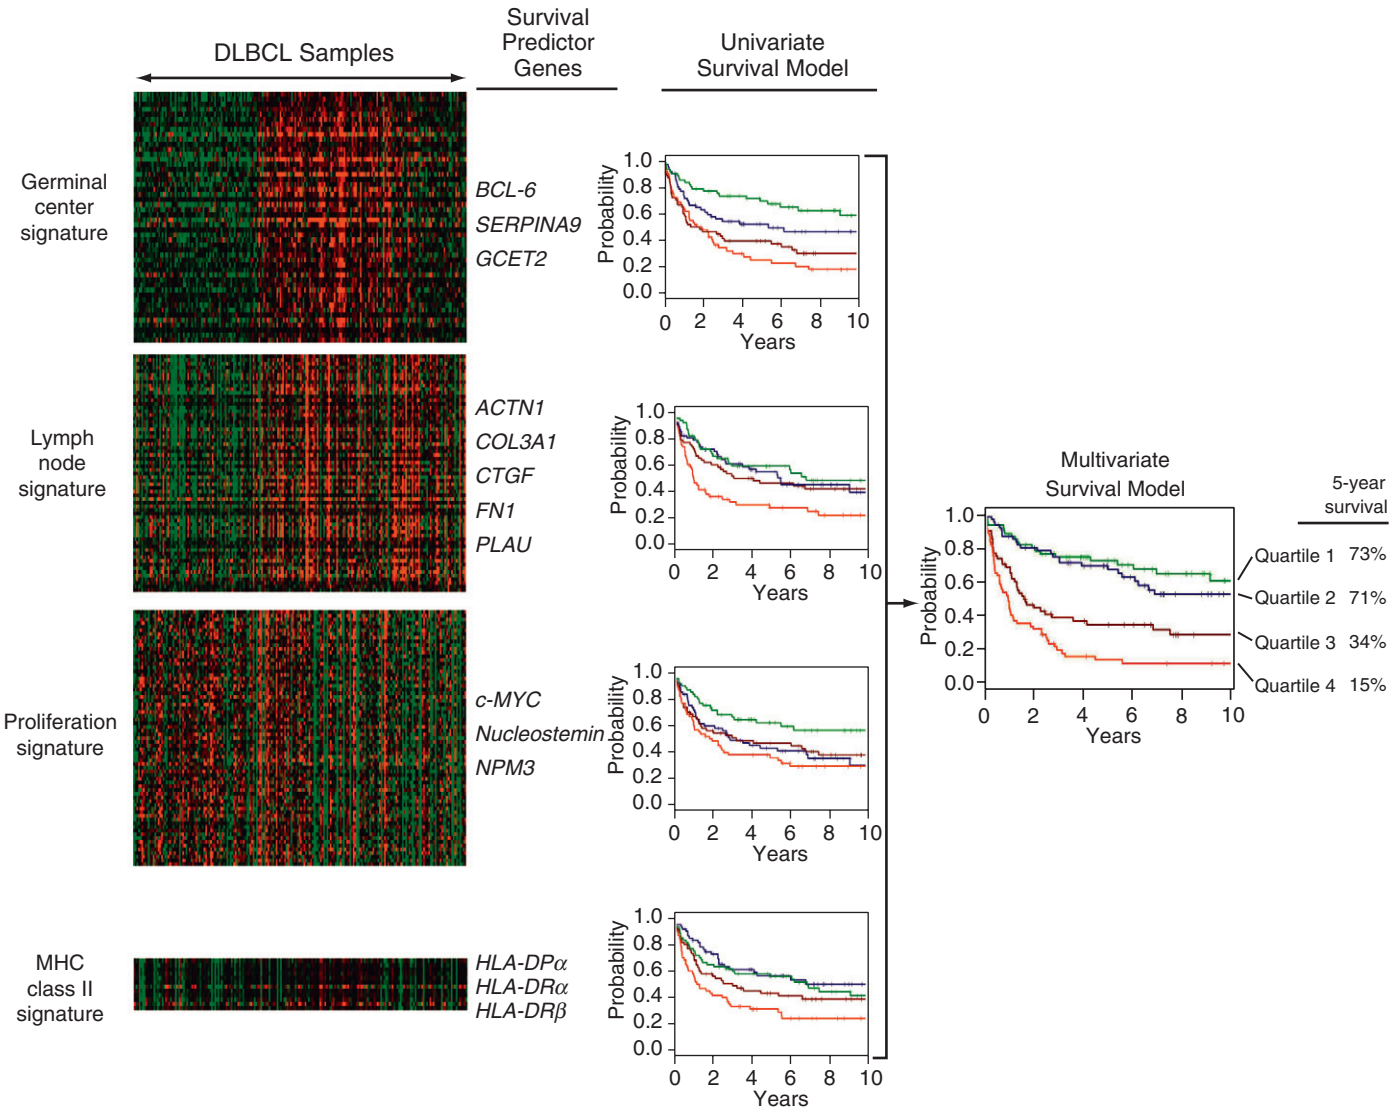

Figure 75-5 GENE EXPRESSION–BASED MODEL OF SURVIVAL AFTER CHEMOTHERAPY FOR DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL). The *left panel* shows the expression of the four gene expression signatures used to create the survival model in DLBCL. Whereas expression of the germinal center, lymph node, and major histocompatibility class II signatures is associated with favorable prognosis, expression of the proliferation signature is associated with inferior survival. Representative genes from each signature used to create the survival model are shown. For each signature, patients were divided into four equal quartiles based on the expression of the signature in their biopsy samples. The four Kaplan-Meier plots in the middle depict the survival of patients in each signature quartile. These four signatures were combined into a multivariate model of survival, and patients were divided into four quartile groups based on this model. The Kaplan-Meier plot at the *right* depicts the survival of each quartile group of the multivariate model. *HLA,* Human leukocyte antigen. *(From Rosenwald, A: The use of molecular profiling to predict survival after chemotherapy for diffuse large-B-cell lymphoma.* N Engl J Med *346:1937, 2002.)*

Conclusions

Diffuse large B-cell lymphoma represents a heterogeneous group of B-cell neoplasms with a distinct underlying biology, prognosis, and response to therapy. Recent genomic approaches to studying DLBCL have identified a number of interesting potential targets for better prognostic stratification and treatment of this lymphoma entity. More work is needed to this end and to better understand the origin of DLBCL and the role of stromal factors in disease progression.

BURKITT LYMPHOMA

Burkitt lymphoma (BL) is a highly aggressive lymphoma entity characterized by a high mitotic rate, extranodal spread, and early death, but it is frequently curable with high-intensity multi-agent chemotherapy. It was first described more than 50 years ago as a disease in young Africans in association with EBV infection. Since then, the sporadic and immunodeficiency-related forms of the disease have been described. Subsequent work has shown that translocation of the *MYC* gene on chromosome 8q24 to the Ig locus occurs in virtually all cases of BL (Figs. 75-6 and 75-7 for an overview of BL). Given the high prevalence of *MYC* rearrangements and the high cure rates observed with chemotherapy, many have studied BL as a model for other B-cell lymphomas.

Overexpression of MYC occurs in association with a GC phenotype. BL tumors typically display the immunophenotypic characteristics of GC B cells, and genetic and genomic studies have reinforced this notion of GC origin. In virtually all cases, rearrangements are found between the MYC locus and one of the Ig genes, most commonly with the IgH locus at 14q32.33 in more than 80% of cases. Alternative rearrangements involving MYC and the κ or λ light chain regions are also noted in the minority of cases. Two different patterns of rearrangement and somatic hypermutation have been noted among the three types of BL. In endemic BL, chromosome 14 breakpoints

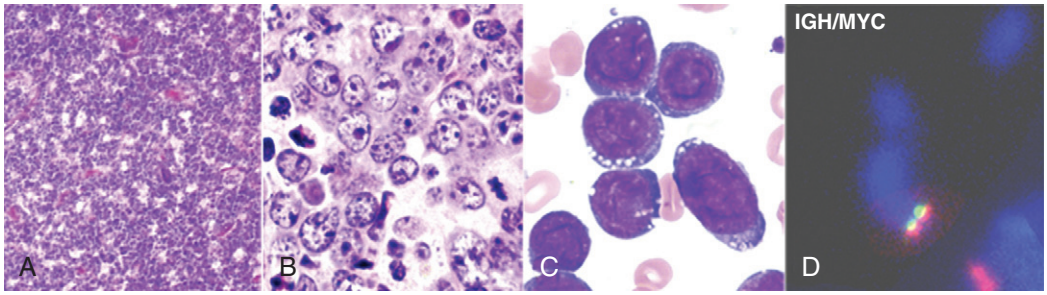

Figure 75-6 BURKITT LYMPHOMA (BL). **A,** A case of BL illustrated at low power showing the "starry sky" appearance. This appearance is attributable to the dense proliferating cells producing the "dark sky," and the scattered lighter staining tingible body macrophages ("stars") phagocytizing dying cells. **B,** Higher magnification image illustrating the syncytia of intermediate-sized cells with coarse chromatin and multiple nucleoli. Note the tingible body macrophage with abundant light cytoplasm and ingested debris *(center bottom).* **C,** Burkitt cells as seen on a Wright-stained bone marrow aspirate in a patient with BL. Notice deep blue cytoplasm with numerous vacuoles. **D,** Fluorescence in situ hybridization with probes to MYC and immunoglobulin h (IgH) illustrate the IgH–MYC fusion. *(Courtesy Dr. Yanming Zhang, University of Chicago.)*

can be mapped to J_H regions, indicating *RAG1*- or *RAG2*-mediated rearrangement occurring at the pro–B cell stage. In contrast, sporadic and immunodeficiency-related BL often demonstrate somatic hypermutation and rearrangement at chromosome 14 breakpoints related in Ig switch regions; this is consistent with GC or memory B-cell origin.

Translocations placing MYC downstream of Ig genes result in massive gene upregulation and oncogenesis by dysregulation of multiple pathways. In normal B cells, MYC regulates B-cell proliferation and differentiation and is tightly regulated by multiple mechanisms, including posttranslational modifications and transcriptional autoregulation and by other factors, including a careful balance of interactions with regulatory proteins. Under normal circumstances, MYC also induces a number of proapoptotic cellular mechanisms, which are then perturbed when MYC is overexpressed by the robust Ig gene promoters existing GC B cells. Constitutive induction of MYC expression in GCs via upstream Ig gene promoter then confers a neoplastic phenotype. Highlighting the complexities of MYC in this setting, even brief reversal of MYC overexpression may induce a reversion of tumors to a benign phenotype; this implies that c-*MYC*–Ig rearrangements might serve as the "switch" that drives BL formation in the context of GCs.

Recently, GEP has further examined the role of MYC in BL and revealed insights into the similarities and differences between BL and other GCB-origin NHLs. This work has further defined the differences between BL and DLBCLs carrying MYC rearrangements because these entities can be difficult to distinguish on histopathologic grounds alone. Although BL is characterized by gene expression profiles consistent with GC origin, a group of genes found in GCB DLBCL, including *LMO2, BCL2, CD80,* and *CD86,* are expressed only weakly in BL. BLs also express low amounts of NFκB and major histocompatibility class I molecules compared with DLBCL. These data also serve to allow the diagnostic distinction of BLs on molecular grounds. In two large studies, a fraction of DLBCLs were classified as BL in instances when there was DLBCL–BL overlap, causing disagreement among pathologists. The outcome with CHOP-like chemotherapy in these instances was associated with poorer survival. Furthermore, classic MYC t(8;14) rearrangements and intermediate molecular phenotypes were also associated with worse overall survival.

The development of a molecular diagnosis for BL aids in distinguishing BL from DLBCL and further illustrates the complexity of *MYC* rearrangements in NHL. Lymphoma entities containing MYC rearrangement in addition to rearrangements in *BCL2* or *BCL6* have been historically termed "double-hit" lymphomas. This subtype frequently has a clinical behavior distant from BL and is often associated with progressive disease, a high International Prognostic Index score, and poor response to intensive chemotherapy regimens. More work regarding this subtype of NHL is needed to understand its pathogenesis.

Aside from gene expression patterns related to GC origin, further genomic alterations may contribute to BL pathogenesis. TP53 is frequently mutated or deleted in a subset of BL tumors. EBV infection is also thought to play a role in the development of BL because virtually 100% of cases of endemic BL and 30% to 50% of all other BLs are associated with EBV positivity. The exact role of EBV in BL is unclear. Endemic BL is frequently associated with endemic malaria, which further suggests a complex interaction of the host immune response with microorganisms and other factors. Other host factors or genomic changes may further contribute to the development of BL.

Further work is needed to define what other genomic changes and host–environmental interactions contribute to the pathogenesis of BL. Ongoing studies seeking to define the entire spectrum of molecular, immunologic, genomic, and epigenetic changes associated with BL pathogenesis may further elucidate this process.

FOLLICULAR LYMPHOMA

Follicular lymphoma is a low-grade B-cell neoplasm that is also characterized by recurrent chromosomal rearrangements involving the IgH locus. It is the most common indolent NHL with more than 16,000 adults diagnosed yearly in the United States. It is characterized by significant heterogeneity with regards to histologic grade and overall survival, with more than 10% of patients surviving at least 15 years after diagnosis. A spectrum of histologic grading based on the density of centroblasts is also characteristic of this disorder, with higher FL grades resembling DLBCL. There is no clear association between grade and clinical outcome in the disease. Some patients with FL experience an aggressive clinical course and transformation to aggressive lymphomas, but others may experience disease progression only after many years with the disease. This review focuses on the classic rearrangements of *BCL2* and the additional molecular changes associated with FL development and with histologic transformation of FL to more aggressive subtypes (Figs. 75-8 and 75-9 for a schematic overview of FL).

BCL2 Rearrangements and Other Genomic Alterations in Follicular Lymphoma

Follicular lymphoma arises from GC B cells that have been immortalized at this stage of B-cell differentiation. Cytogenetic studies performed in the early 1970s defined a recurrent translocation involving the long arms of chromosomes 14 and 18 in more than 90% of FL cases. Further investigation revealed that this places the gene encoding the important antiapoptotic gene *BCL2* downstream of the Ig heavy chain transcriptional regulators. The BCL2 protein inhibits the

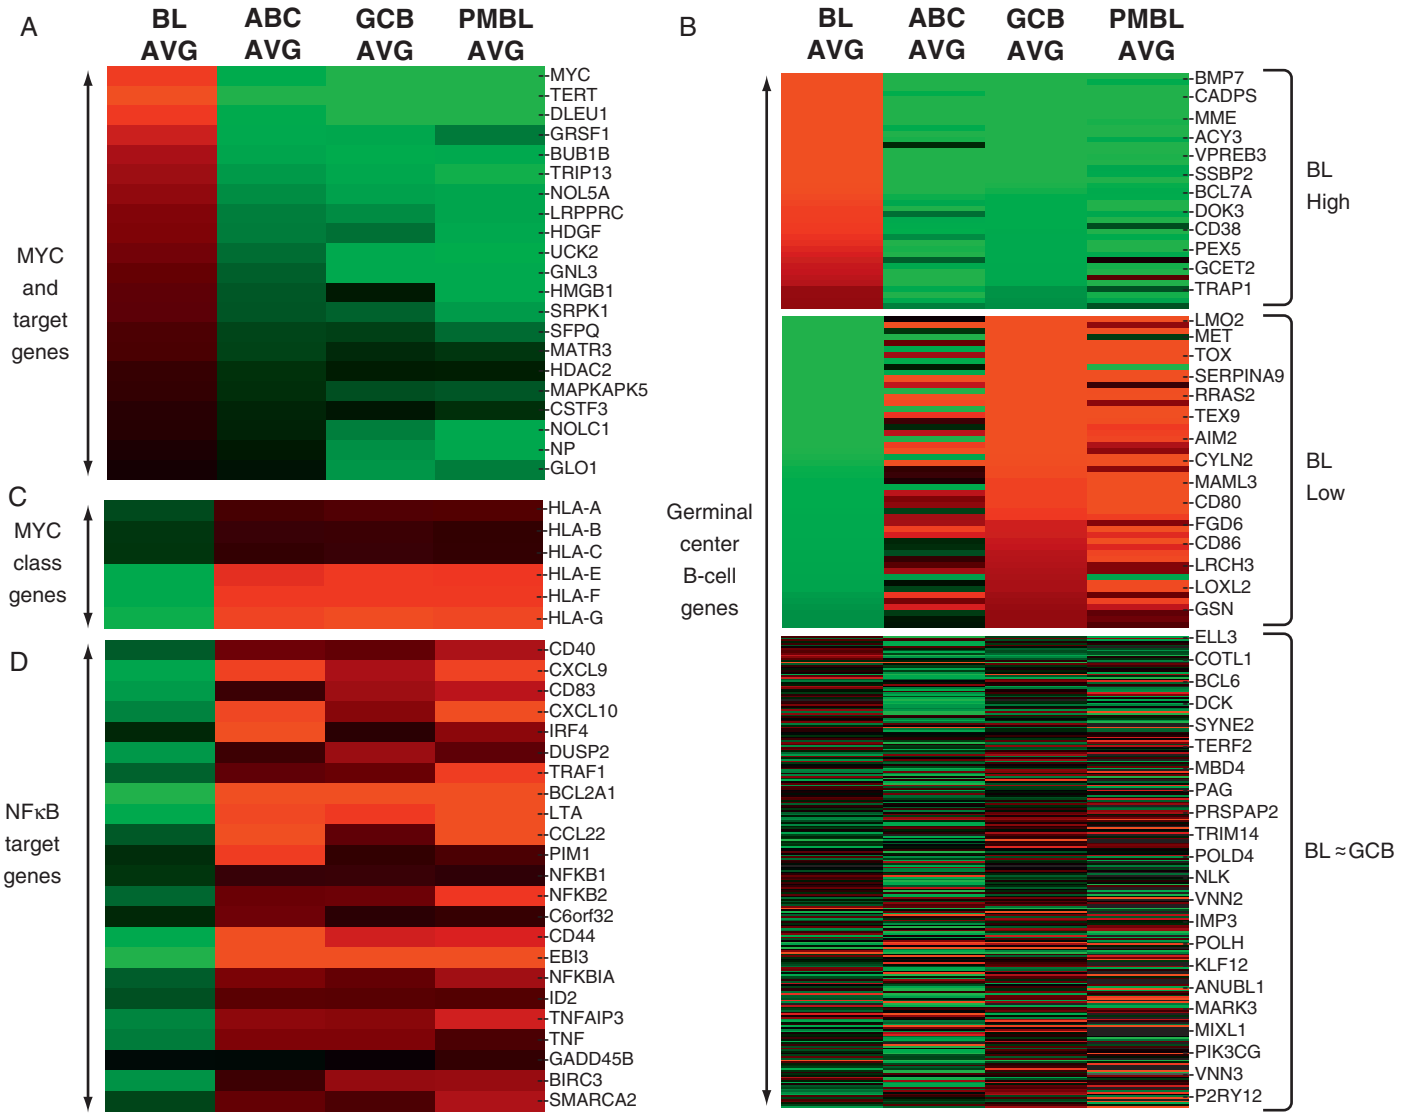

Figure 75-7 Relative expression of genes that distinguish Burkitt lymphoma (BL) from subgroups of diffuse large B-cell lymphoma (DLBCL)—activated B cell–like (ABC) DLBCL, germinal center B (GCB) DLBCL, and primary mediastinal B-cell lymphoma (PMBL)—is categorized into gene expression signatures: c-myc and its target genes **(A)**; genes that are expressed in normal germinal center (GC) B cells **(B)** and are expressed more highly (BL-high), less highly (BL-low), or equivalently (BL~GCB) in BL than in GCB DLBCL; major histocompatibility class I genes **(C)**; and genes targeted by the nuclear factor kappa-B (NFκB) signaling pathway **(D).** GC B-cell signature genes are those that were overexpressed in normal GC B cells, compared with blood B cells. The "BL-high" genes were expressed at levels twice as high in BL as in GCB DLBCL (P <.001). The "BL-low" genes were expressed at levels twice as high in GCB DLBCL as in BL (P <.001). The expression levels of the "BL~GCB" genes did not differ significantly between the two lymphoma subtypes. *(From Dave SS, Fu K, Wright GW, et al: Lymphoma/Leukemia Molecular Profiling Project: Molecular diagnosis of Burkitt's lymphoma.* N Engl J Med *354:2431, 2006.)*

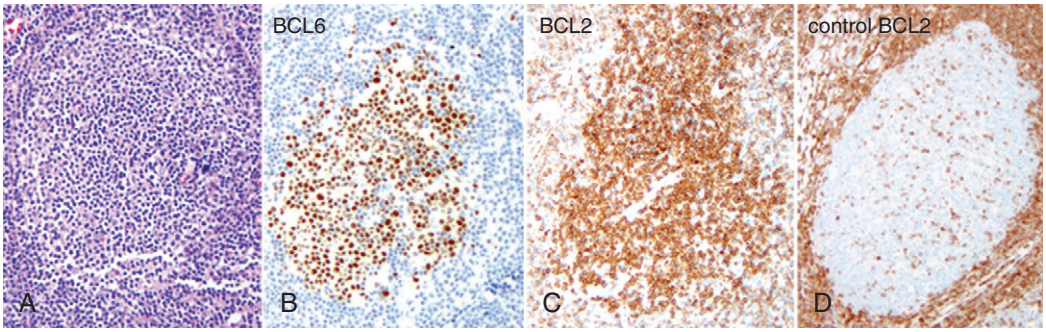

Figure 75-8 FOLLICULAR LYMPHOMA (FL). Details from a case of FL, grade 1 of 3 associated with t(14;18) (q32;q21). Malignant follicle **(A)** with immunohistochemical stains for the germinal center marker, BCL6 **(B),** and BCL2 **(C).** Note the overexpression of BCL2 compared with a reactive follicle **(D).**

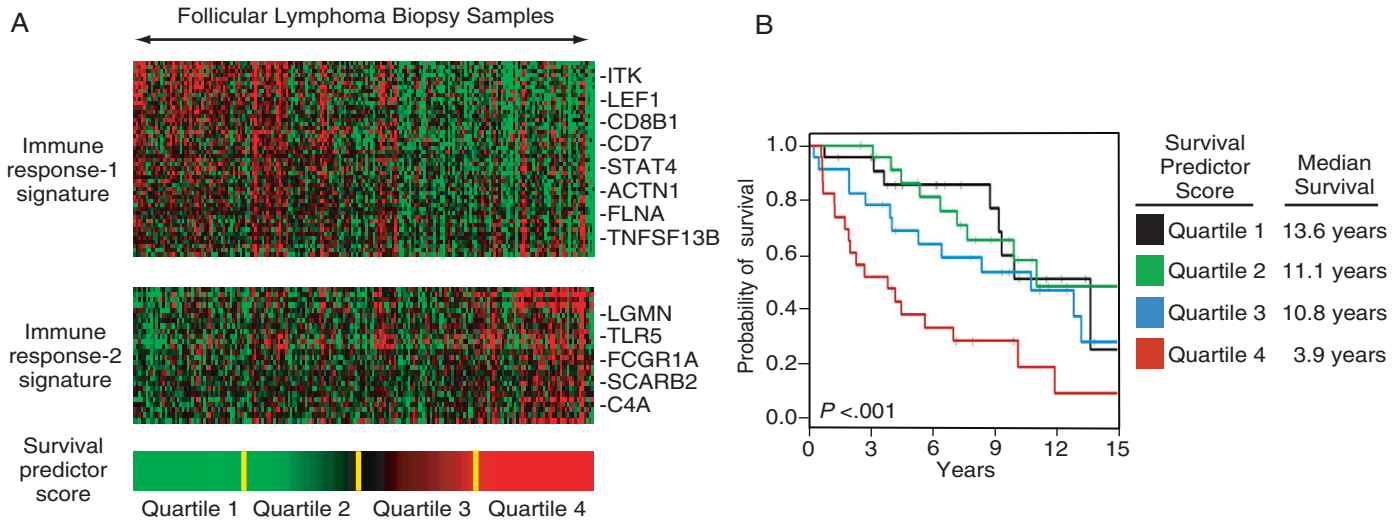

Figure 75-9 SURVIVAL IN FOLLICULAR LYMPHOMA (FL) CAN BE PREDICTED USING FEATURES OF THE TUMOR MICROENVIRONMENT. **A,** Two sets of coordinately expressed genes, termed the *immune response-1* and *immune response-2 signatures*, are associated with survival in FL. The expression pattern of each gene in these two signatures is shown for FL biopsy samples. Expression of the immune response-1 signature is associated with favorable survival after diagnosis, and expression of the immune response-2 signature is associated with adverse survival. These signatures are combined into a multivariate model of survival that generates a survival predictor score for each patient. Patients are ranked according to this survival predictor and divided into four equal quartiles as shown. **B**, Kaplan-Meier plot of overall survival of patients in the four quartiles of the survival predictor. *(**A,** see Dave SS, Wright G, Tan B, et al: Prediction of survival in follicular lymphoma based on molecular features of tumor-infiltrating immune cells. N Engl J Med 351:2159, 2004.)*

release of cytochrome c from mitoch in the process of apoptosis. In normal GCs, *BCL2* is essentially absent because selection of B-cell clones via apoptosis is an important step in the production of high-affinity Ig idiotypes. The t(14;18)(q32.3;q21.3) appears to be mediated by *RAG1/RAG2* in pre-GC B cells because *BCL2* is most often found juxtaposed to J chain exons. Isolated t(14;18) is not sufficient to induce FL because transgenic mice bearing this translocation develop lymphoid hyperplasia but require other genetic lesions to develop FL. Additionally, B cells with t(14;18) can be isolated from apparently normal individuals who never develop lymphoma, and *in situ* follicular hyperplasia with BCL2 overexpression has been noted on examination of otherwise normal lymph nodes. This suggests that other lesions must be acquired for development of FL; a preponderance of evidence suggests this occurs in GCs. Histologically, FL is characterized by an abnormal follicular architecture containing neoplastic cells. The follicles loosely resemble GCs but usually lack an appreciable mantle zone but generally occur in close proximity to follicular T-helper cells expressing CD3, CD4, CD57, PD1, and CXCL13. FL usually exhibits a CD10+BCL6+IRF8+ GC-like phenotype in association with ongoing somatic hypermutation, confirming GC or post-GC origin. One obvious hypothesis is that BCL2 overexpression dysregulates apoptosis such that GC transition and SHM result in further genomic and epigenomic changes that result in FL. This framework might need to be reexamined in the small proportion of FL cases that do not express BCL2.

Although BCL2 is thought to have a critical role in development of FL, nearly 30% of grade 3A and a majority of grade 3B FLs are t(14;18) negative. Alternative rearrangements involving the κ or λ light chains and *BCL2* may occur, but many t(14;18) FLs do not express BCL2. These entities express a post-GC CD10-IRF4-phenotype with 3q27/*BCL6* rearrangements and are associated with lower chemotherapy response rates as well as worse overall survival compared with t(14;18)-positive FLs. It is not clear how this subset of FL evolves from normal B cells, but this immunophenotype suggests a late- or post-GC origin. GEP and analysis of miRNA profiles of FL confirm this association. Leich et al analyzed gene expression profiles of 184 grade I-3A FLs, of which 17 were t(14;18) negative (six of these rearrangement-negative FLs still overexpressed BCL2). Analysis of this data showed enrichment of signatures associated with activated B cells, including NFκB signaling, and those associated with cell cycle, proliferation, and the tumor microenvironment. A study involving a similar cohort showed that a pattern of 17 miRNAs was differentially expressed between translocation positive and negative phenotypes. A group of five miRNAs was found to be downregulated in the t(14;18) group, and this correlated to overexpression of genes related to proliferation, apoptosis, and differentiation. Thus evidence for a post-GCB origin of t(14;18) translocation–negative FLs exists at the gene expression level. Further work is needed to fully understand how BCL2-negative FL develops.

Similar work with BCL2-positive FL has revealed the additional steps required for FL development after t(14;18). Further genomic changes and host factors have also been delineated for DLBCL arising from FL. Conventional cytogenetic studies in FL reveal recurrent duplications of 1p36 and 6q and gains of chromosomes 2, 8, 17, 21, and X. Additionally, SHM appears to affect glycosylation status of surface Ig, implicating BCR signaling in FL pathogenesis. Histologic transformation is associated with further mutations or deletions in *TP53* and *p16* and appears to occur by distinct mechanisms involving either clonal evolution or by transformation of a putative progenitor FL stem cell. Acquired rearrangement of the MYC oncogene can also occur and has been associated with an aggressive plasmablastic phenotype. Stromal factors with FL tumors also likely play a key role in FL propagation and have been studied as having prognostic consequence in FL as well.

Tumor Microenvironment and Survival in Follicular Lymphoma

Just as the lymphoid microenvironment is integral to the formation and function of GCs and immune factors predict survival in DLBCL, FL development appears to depend on stromal factors and the host immune response. In the largest study examining this relationship Dave et al performed gene expression analysis using whole-genome microarrays on 191 FL specimens with the goal of determining genomic predictors of survival. Genes identified were stratified into two groups based on correlation of expression with patient outcome (gene sets associated with good prognosis or poor prognosis). Hierarchical clustering then identified five survival gene sets within each of these groups; analysis revealed that a combination of two gene sets (immune response-1 and immune response-2) formed the best model for prediction of survival. Interestingly, immune response-1 consists of genes *(CD7, CD8B1, ITK, LEF1, STAT4)* associated with specific T-cell populations and macrophages. Conversely, immune response-2

consisted of genes found in dendritic cells and macrophages and was devoid of genes expressed by T-cell subsets. Comparison with T-cell genes suggested a complex relationship with immune response-1 rather than a simple preponderance of T cells in the tumor biopsy.

Several hypotheses can be generated regarding the implication of these findings in FL biology. Given the relationship of genes involved in the immune response to survival, a direct impact of T-cell effector subsets in FL tumors could be one conclusion. Conversely, poor-risk tumors may be those that have become independent of FL follicles and therefore are more aggressive; this may be reflected in the variability of the immune response gene signatures seen across FLs. The impact of immune factors has been seen in other studies as well because survival may depend on FoxP3+ regulatory T-cell subsets, infiltration of macrophages, and the peripheral total monocyte count. Further work is needed to more clearly identify how the FL microenvironment impacts FL development and progression and to clarify whether manipulation of the immune compartment may be used therapeutically.

MANTLE CELL LYMPHOMA

Mantle cell lymphoma (MCL) is characterized by the chromosomal translocation t(11;14)q13;q32, which places cyclin D1 under the transcriptional control of the IgH promoter. MCL is predominantly a disease of elderly men and is characterized by a rather short median survival of 5 to 7 years. Histologic evaluation divides MCL into classic and blastoid variants, with the blastoid subtype having worse survival. Subgroups can also be defined on the basis of somatic mutations in the IgH loci because Ig-mutated tumors tend to have a more indolent disease as is the case with chronic lymphocytic leukemia (CLL), another CD5+ neoplasm. This suggests two disparate origins for MCL with one subtype arising from pre-GC B lymphocytes and another stemming from cells that have encountered antigen and consequently have undergone SHM (see Fig. 75-10). Genomic approaches have also identified molecular profiles delineating MCL from histologically similar neoplasms and identified factors associated with survival. Notably, a minority of patients with MCL are cyclin D1 negative, and GEP has been useful in identifying this entity; further work in this area has identified numerous genomic lesions and molecular pathways involved in MCL. Herein the pathogenesis of MCL is reviewed focusing on the genomic and molecular basis of this disease.

Cyclin D1 and Mantle Cell Lymphoma

The genetic hallmark of MCL, the t(11;14) (q13; q32) translocation, juxtaposes the *CCND1* gene to the IgH locus, leading to overexpression of the cell cycle regulator cyclin D1. The three D-type cyclins (D1, D2, and D3) play an important role in cellular proliferation by propelling cells from G_1 to S phase of the cell cycle. Each forms heterodimers with the cyclin-dependent kinases CDK4 and CDK6, thus forming active kinase complexes. These complexes inactivate retinoblastoma protein (Rb) and bind to p27kip1, which functions to facilitate cell entry into the S phase of the cell cycle and consequent proliferation.

Cyclin D1 is not expressed in normal lymphocytes, and t(11;14) thus represents a pathogenic event in the origin of MCL. The gene encoding cyclin D1 *(CCND1)* consists of five exons that are alternatively spliced into two isoforms, cyclin D1a and D1b. Cyclin D1b does not appear to play a role in MCL. The proliferative capacity of MCL tumors appears closely tied to the degree of cyclin D1a overexpression. MCLs carry mutations in the 3′ untranslated region of *CCND1* that serve to stabilize cyclinD1a transcripts by removing miRNA (miR15/16) binding sites and deleting mRNA destabilizing elements. These sequences usually result in cyclin D1a being an unstable entity, with a half-life of less than 1 hour, but in MCL, these deletions or mutations result in cyclin D1a accumulation and increased cellular proliferation. Additional mutations in the translated regions of cyclinD1 result in protein stabilization through the blockade of GSK3β-mediated nuclear export of cyclin D1.

A minority of patients with MCL are cyclin D1 negative and are alternatively characterized by overexpression of cyclin D2 or D3 and cyclin D2. These derangements serve to deregulate the G_1–S transition in a manner similar to t(11;14) and highlight the theme that MCL is a disease created by cyclin complex–mediated cell cycle progression aided by upregulation of several molecular pathways associated with cellular proliferation and genomic instability.

Secondary Genomic Alterations in Mantle Cell Lymphoma

Beyond t(11;14), MCL is characterized by extensive genomic instability relative to other NHLs, and a variety of genetic lesions appears to drive proliferation of these tumors. Recurrent chromosomal losses, gains, and amplifications are seen in MCL, and many of these affect a large proportion of cases. Secondary genetic instability may occur

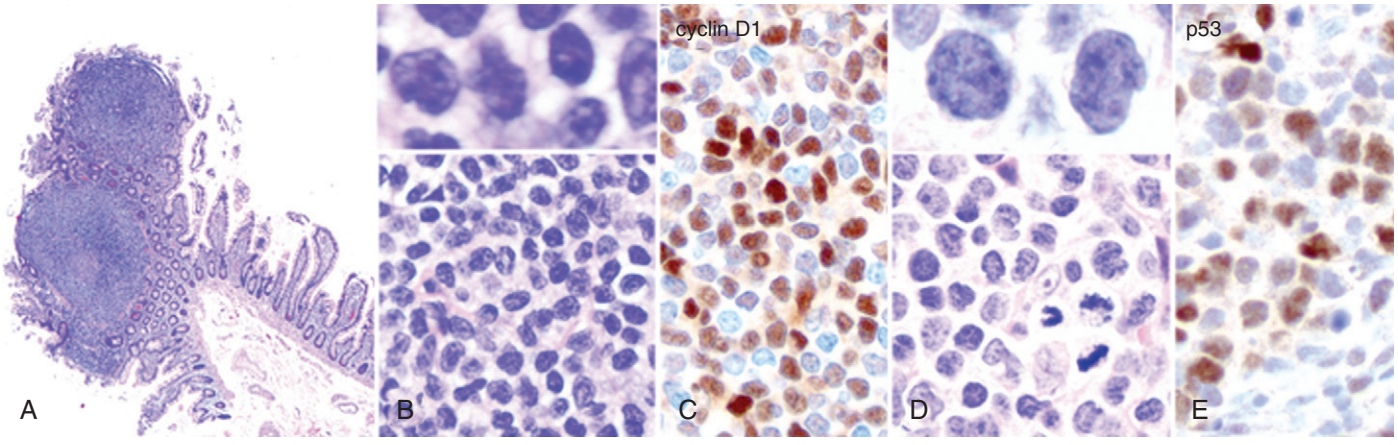

Figure 75-10 MANTLE CELL LYMPHOMA (MCL). **A,** A case of MCL presenting as lymphomatoid polyposis. **B,** The lymphoma cells are small to intermediate in size and have irregular nuclear contours and condensed nuclear chromatin. The cells were CD19$^+$, monoclonal B cells with λ light chain restriction, coexpression of CD5, FMC-7, and lack of CD23. **C,** The cells showed cyclin D1 expression by immunohistochemical staining. The t(11;14)(q13;q32) was detected by conventional cytogenetic analysis. **D,** In comparison, the blastoid variant of MCL has larger cells with a high mitotic rate and fine chromatin. **E,** These cases frequently overexpress p53 and are associated with a complex karyotype, including t(11;14).

as a result of aberrant DNA replication in the setting of deregulated S phase transition mediated by cyclinD1–CD4-complexes. Acquired lesions in genes mediating cellular response to DNA damage and microtubule dynamics may contribute to the accumulation of these alterations as well.

Many (30%–50%) of MCL cases are characterized by mutations or deletions in the DNA damage response pathway mediated by ATM and TP53 or modifiers of this pathway such as MDM2 and p14/ARF. *ATM* is often mutated with loss of the other chromosomal allele. TP53 may also be downregulated in these tumors via similar mechanisms, and overexpression of TP53-negative regulators MDM2 and MDM4 also occurs via copy number amplification. These overall serve to deregulate important cellular machinery involved in DNA damage repair, apoptosis, and cell cycle arrest, leading to increased cell cycle progression and proliferation in MCL. Further deletions at 9p21 occur frequently in MCL and serve to enhance cell cycle progression and block apoptosis. The 9p21 locus encodes p16(INK4a) and p14(ARF), which function as tumor suppressors. p16(INK4a) inhibits CDK 4/6 complex binding to cyclin D1, which results in decreased cell cycle progression. Deletion of p16(INK4a) in the setting of t(11;14) enhances proliferation in MCL and has been associated with worse overall survival. The function of p14(ARF) in MCL pathogenesis is less clear, but p14(ARF) blocks MDM2-mediated TP53 ubiquitination; p14(ARF) has other effects on cellular proliferation that usually work in a homeostatic pattern. Interestingly, cyclin D1 levels and INK4a/ARF deletions both correlate to a MCL proliferation signature created using GEP. Using a similar strategy, cyclin D1 expression levels and the presence of INK4a/ARF deletion have been used to create a predictor of overall survival using a cohort of MCL patients. Survival among groups stratified by this approach varies widely (from 6-7 years to <10 months), which confirms the importance of involvement of genes involved with the cell cycle and proliferation in MCL. This parallels the experience noted with histologic markers of tumor proliferation because Ki-67 (a marker of actively dividing cells) and the presence of blastoid features have previously been shown to correlate with worse outcomes.

When considered together, the recurrent deletions and mutations noted in MCL illustrate the importance of unchecked cell cycle progression in this disorder. DNA instability is another hallmark of MCL that appears to result from the blockade of cell cycle checkpoints in the setting of ongoing DNA damage. These factors are intertwined in a complicated fashion in MCL and further work to upregulate several diverse molecular pathways involved in cellular proliferation and survival.

Molecular Pathways and Profiles in Mantle Cell Lymphoma

A variety of molecular pathways have recently been described as being active in MCL. These include signaling pathways facilitating cellular proliferation, avoidance of apoptosis, evasion of immune editing, and cellular microenvironment interactions. As in other NHLs, GEP has been used to define a molecular diagnosis of MCL and identify genes and molecular pathways involved in its pathogenesis (Fig. 75-11).

Genomic approaches identify a subset of MCL that is cyclin D1 negative and has features similar to other CD5+ B-cell neoplasms such as CLL. Although such cases are indistinguishable by histologic analysis, GEP demonstrates that these tumors express gene signatures that are otherwise nearly identical to cyclin D1+ MCL but lack the classic t(11;14) rearrangement. Overexpression of other D cyclins (cyclin D2 or D3) via rearrangement, amplification, or other mechanisms is found in many of these cases; this is consistent with the underlying theme that MCL is a disease of disordered cell cycle progression. Using a similar approach, *SOX11* has been identified as a sensitive and specific marker of MCL regardless of cyclinD1 expression status. *SOX11* encodes an HMG-box transcription factor that regulates embryogenesis and is important in neural development. Because greater than 90% of MCL specimens overexpress *SOX11* and this finding is rare in histologically similar NHLs, *SOX11* is a potentially useful marker for improving the diagnosis of MCL. *SOX11* has also been incorporated into prognostic models of MCL using histologic, clinical, and GEP data. Reports regarding the clinical significance of *SOX11* have been conflicting. Thus further work is needed to understand the molecular mechanisms underlying *SOX11* expression in MCL and the implications in this disease.

Mantle cell lymphoma has also been characterized by expression of several molecular pathways that enhance cellular proliferation and metabolism and are tightly intertwined with abnormalities in cell cycle regulation. *Wnt 3* is a consistently overexpressed gene in MCL, and abnormal Wnt signaling may be one way in which MCLs bypass negative feedback loops controlling differentiation. Proliferation in MCLs may also depend on Wnt–B-catenin signaling, but the impact of this pathway on patient survival or as a therapeutic target in MCL is unknown. Similar to ABC DLBCLs, the NFκB pathway is also active in MCL, and crosstalk between proliferation signaling between this pathway PI3K/AKT/mTOR and cell cycle signaling also appears to be important. Importantly, phosphatase and tensin homologue (PTEN), a molecule that has important roles in providing negative feedback to the mTOR pathway is also commonly deleted or acquires loss of function mutations in MCL. Taken together, these facts reinforce the fact that abnormalities in several diverse signaling pathways are required beyond t(11;14) for MCL to form. Further work is needed to define how to use these findings to build better prognostic models in this disease, and studies investigating the therapeutic utility of targeting these pathways are beginning.

OTHER NON-HODGKIN LYMPHOMAS

Gene expression profiling and high-throughput sequencing have been applied to other lymphomas in manners similar to the subtypes already described. Important discoveries regarding other NHLs such as marginal zone lymphomas, lymphoplasmacytic lymphoma, and peripheral T-cell lymphomas (PTCLs) have refined our understanding of how these diseases develop. Recurrent mutations in genes and involvement of molecular pathways governing control of apoptosis, cellular proliferation, and metabolism are recurrent themes in these NHL subtypes as well as those described earlier. In addition to being found in DLBCLs, *MYD88* L265P mutations have been reported in virtually all cases of lymphoplasmacytic lymphoma (Waldenstrom macroglobulinemia) and may serve as a marker to differentiate this disease from other indolent lymphomas. *NOTCH2* mutations have been noted in a subset of marginal zone lymphomas and have been found in DLBCLs and other NHLs. Gene clusters have also been developed for T-cell lymphomas and identify angioimmunoblastic T-cell lymphoma (AITL) as an entity distinct from other PTCLs; this work also has shown upregulation of genes involved in NFκB signaling in AITL. A subset of PTCL is characterized by t(2;5) (p23;q35), which joins the anaplastic lymphoma kinase-1 gene *(ALK)* next to *NPM-1* at 5q35. This creates an aberrant tyrosine kinase that appears to have a number of downstream transforming effects. ALK positivity is generally associated with response to cytotoxic chemotherapy in PTCL; however, better molecular predictors of response are needed. Whereas NFκB gene signature expression also correlates to improved survival in PTCL, tumors that exhibit increased markers of proliferation are associated with poor outcomes, as in other NHLs. Given that rarity of these tumors, it is difficult to make further associations between molecular markers and outcomes.

FUTURE DIRECTIONS

Non-Hodgkin lymphoma represents a complex group of related neoplasms that have quite disparate molecular characteristics. Given the lack of modifiable risk factors and varied prognosis with standard treatment (chemoimmunotherapy), a better understanding of the processes driving NHL is needed. Advances in technology have recently allowed whole-genomic surveys to identify the role of altered

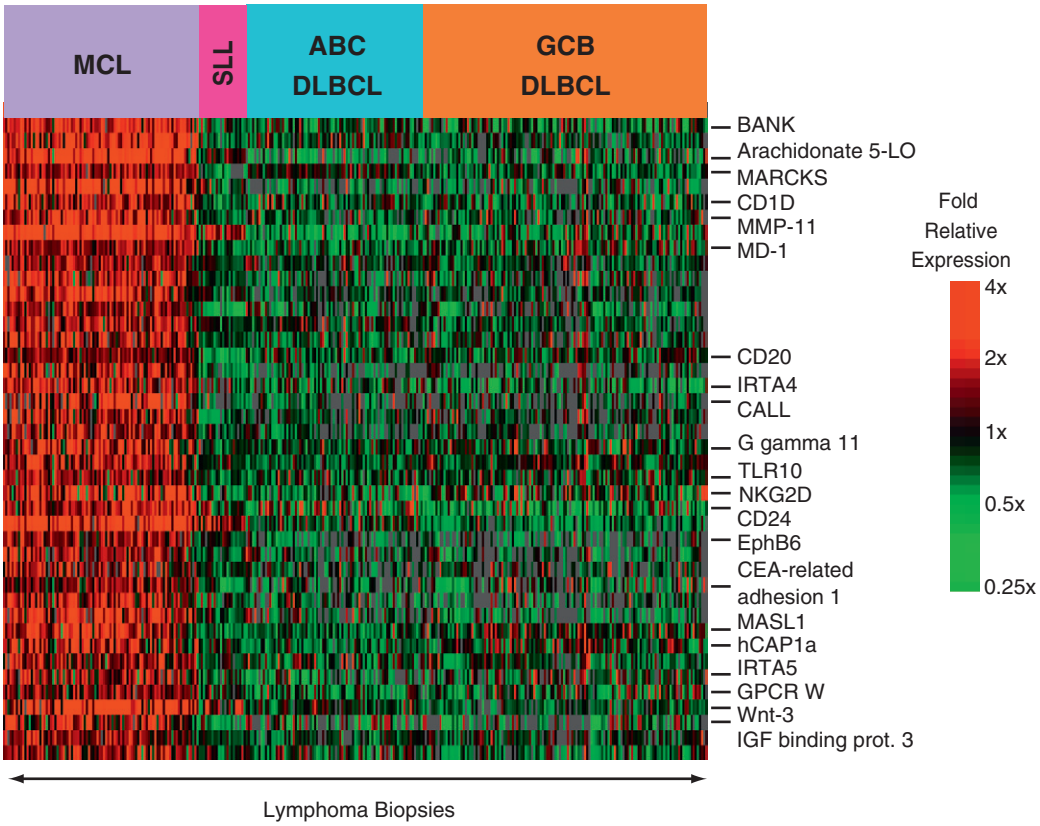

Figure 75-11 HIERARCHICAL CLUSTERING OF EXPRESSION MEASUREMENTS FROM 42 MANTLE CELL LYMPHOMA (MCL) SIGNATURE GENES THAT ARE MORE HIGHLY EXPRESSED IN MCL SAMPLES COMPARED WITH SMALL LYMPHOCYTIC LYMPHOMA (SLL), ACTIVATED B CELL–LIKE (ABC) DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL), AND GERMINAL CENTER B (GCB) DLBCL SAMPLES. Each column represents a single lymphoma specimen, and each row represents expression of a single gene. *Red squares* indicate increased expression, and *green squares* indicate decreased expression relative to the median expression level according to the color scale shown. *(From Fu K, Weisenburger DD, Greiner TC, et al: Lymphoma/Leukemia Molecular Profiling Project: Cyclin D1-negative mantle cell lymphoma: A clinicopathologic study based on gene expression profiling.* Blood *106:4315, 2005 and Rosenwald A, Wright G, Wiestner A, et al: The proliferation gene expression signature is a quantitative integrator of oncogenic events that predicts survival in mantle cell lymphoma.* Cancer Cell *3:185, 2003.)*

genetics, transcription, and epigenetic regulation as contributors to the observed lymphoma phenotypes. This work will serve as the starting point for the unraveling of new diagnostic and prognostic markers, as well as therapeutic targets in a group of diseases in which such options are urgently needed.

CHAPTER 76

CHRONIC LYMPHOCYTIC LEUKEMIA

Thomas S. Lin, Farrukh T. Awan, and John C. Byrd

Over the past several decades, major advances have come in understanding both the biology that ultimately has translated to both helpful diagnostic tests and improved therapy for chronic lymphocytic leukemia (CLL). The plethora of information about CLL has increased dramatically and made management of what was a relatively straightforward disease quite complex. The authors herein provide a reference source focused on critical issues in clinical management of CLL that will hopefully help.

EPIDEMIOLOGY

Chronic lymphocytic leukemia is one of the most common types of leukemia in the Western Hemisphere. SEER estimates for 2010 indicated that approximately 14,570 patients (8520 men and 6050 women) would be diagnosed in the United States and that 4380 patients would die from CLL in 2010. The median age at diagnosis for CLL was 72 years from 2000 to 2005, according to the SEER database. The incidence of CLL increases proportionately by decade, as shown in Fig. 76-1. This figure illustrates that CLL is a very uncommon diagnosis before 45 years of age and infrequent (30% of total patients diagnosed) in patients before 65 years of age. The age-adjusted incidence rate was 4.2 per 100,000 men and women per year; 0.46% of men and women born in 2008 are expected to be diagnosed with CLL during their lifetime. The extended time of survival after diagnosis at 5 years is 80.8%, which explains the estimated prevalence of 105,643 patients living with CLL in the United States currently. Similar to other types of leukemia, the risk of dying from disease-specific causes increases proportionately with increasing age. Another analysis of the SEER database comparing outcome of elderly patients with CLL with age- and sex-matched healthy control participants demonstrated that CLL has the greatest impact on survival in the most elderly group of patients. However, even for patients diagnosed with CLL before the age of 50 years, Montserrat and colleagues demonstrated that the median expected life span is only 12.3 years compared with 31.2 years in age-matched control participants. Thus CLL is a significant health problem affecting all ages of patients with this disease.

Chronic lymphocytic leukemia is more common in men than women. Women diagnosed with CLL have 5- and 10-year overall survival (OS) rates that exceed those of men. CLL is most common in whites and decreases in frequency in a descending order among blacks, Hispanics, American Indians and Native Alaskans, and Asians and Pacific Islanders. The rarity of CLL among Asians and Pacific Islanders persists even in immigrants from these areas who have migrated to the Western Hemisphere. This implicates a possible genetic predisposition to the development of CLL. The relationship of environmental factors such as exposure to benzene and other chemicals to the development of CLL is not clearly defined. However, CLL is recognized as a service-connected illness among Vietnam War veterans who were exposed to Agent Orange. For patients in the theatre of the Vietnam conflict, it is important to identify this because additional compensation from the U.S. Veterans Administration is possible. Occupational or environmental exposure to radiation does not appear to predispose patients to a higher risk of developing CLL. For example, although the frequency of acute myeloid leukemia (AML), chronic myeloid leukemia (CML), and acute lymphoblastic leukemia (ALL) were increased among survivors of the atomic bomb at Hiroshima, no increase in CLL was appreciated. Recent studies of leukemia rates in inhabitants around the Chernobyl nuclear reactor accident site have supported this notion, where essentially all other types of leukemia were increased with the exception of CLL.

FAMILIAL CHRONIC LYMPHOCYTIC LEUKEMIA

Up to 10% of CLL patients have a first- or second-degree relative with CLL, making CLL one of the most common types of malignancy with familial predisposition. Newer studies identifying an even higher frequency of monoclonal B-cell lymphocytosis (MBL) in these families provides further evidence of inheritance in a subset of patients. Unlike other types of familial cancer, it is very uncommon for CLL patients to have large pedigrees with many affected distant relatives throughout an extensive family tree. Rather, the more common finding is for most patients to have one or two first- or second-degree relatives with this diagnosis. Large case-control studies concluded that the risk ratio (RR) for first-degree relatives of CLL probands to also have CLL was higher than that for most other cancers. Although the average RR for all cancers in a U.S. study was approximately 2.1, CLL showed an RR of 5.0, the fourth highest of all cancers. Relatives of patients with CLL also appear to have a higher frequency of other lymphoproliferative disorders and autoimmune diseases. Unlike a variety of other cancers that have known predisposing genes, identification of divergent genes in CLL has been generally elusive. To date, only a single germline mutation of death-associated protein kinase (DAPK) and LEU7 has been convincingly linked to familial predisposition in a single CLL family but not identified by others in additional families. Most other studies have been limited by weak evidence for linkage, and the occurrence at many loci was different between the studies. Two loci at chromosome bands 11p11 and 13q21 were backed by statistically significant evidence, but no genes at these sites have been implicated in familial CLL. This brings forth a common theme of divergent pathogenesis in familial predisposition of CLL. In a very small number of isolated families, there are likely driver mutations with a dominant pattern of inheritance such as the DAPK1 and LEU7 family. In conjunction with this, there are many collaborating, low phenotype associated genes in the majority of families in which familial disease is present, thereby explaining the failure of linkage studies to identify specific abnormalities. It is likely that significant advances will come over the next decade in identifying these collaborating genes with the ability to do whole-genome sequencing in large cohorts of patients. The role of anticipation in identifying other family members has been reported by several groups; patients with such a family history are generally diagnosed a median of 10 years earlier than other patients. However, other clinical features of CLL at diagnosis do not appear to be different. Thus patients with familial CLL do not appear to be genetically or clinically different from individuals with sporadic CLL.

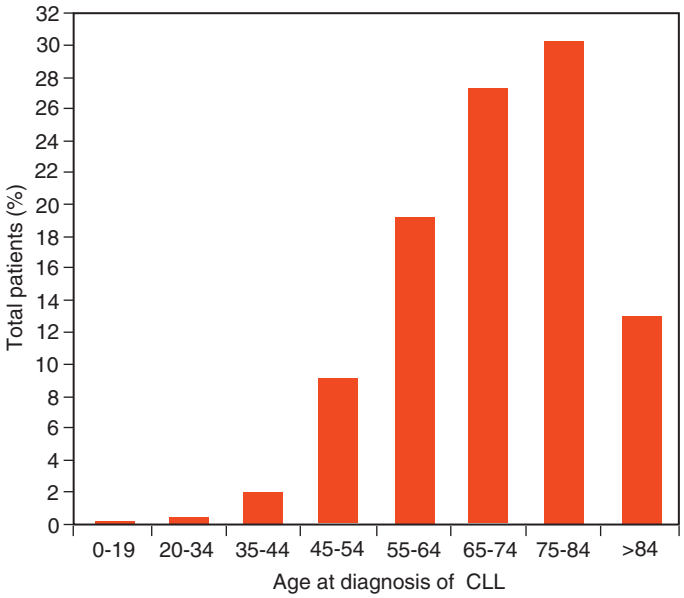

Figure 76-1 GRAPH SHOWING THAT CHRONIC LYMPHOCYTIC LEUKEMIA (CLL) IS A VERY UNCOMMON DIAGNOSIS BEFORE AGE 45 YEARS AND INFREQUENT (30% OF TOTAL PATIENTS DIAGNOSED) BEFORE AGE 65 YEARS.

PATHOBIOLOGY

The complexity of the biology of CLL has become increasingly apparent as the knowledge of the basic science of this disease has expanded. Despite these advances, many questions remain unsolved, including (1) the cell of origin from which CLL is derived, (2) the existence of a CLL stem cell as occurs in other leukemias, (3) the biological etiology of the divergent natural histories of IgV_H-mutated versus unmutated CLL, and (4) the existence and identification of infectious or other naturally occurring antigens that may drive the B-cell clone in this disease. Nonetheless, significant advances in our understanding of the roles of cytogenetics, immunology, and other relevant biological markers in predicting the natural history of disease progression and response to therapy in CLL make an understanding of the basic biology of CLL increasingly relevant and important to clinicians caring for CLL patients.

For many years, CLL was believed to represent a single disease that had a varied natural history. Basic research focused on understanding (1) the normal cell of origin from which CLL is derived, (2) the function of the B-cell receptor (BCR) in CLL, (3) the maturational point in B-cell development at which CLL occurs, and (4) the relevance and contribution of a self- or acquired antigen to driving the disease. The normal counterpart to the cell of origin of transformed CLL remains unknown. For many years, it was believed that CLL was not derived from a clonal stem cell, based on the inability of the leukemia cells to engraft and recapitulate the disease when tumor cells are inoculated or transplanted into immunocompromised mice. However, a recent seminal paper demonstrated that CD34-positive hematopoietic stem cells from CLL patients have a higher number of cells with B-lymphoid progenitor phenotype and develop clonal B cells characteristic of CLL when engrafted into immunocompromised mice. Notably, the CLL cells developing in these mice did not have the genetic features of the patient's CLL, suggesting that additional transforming event(s) in the clonal CLL cells occur(s). In addition, several whole exon and genome sequencing projects in CLL have identified genes, such as *NOTCH1* and *SF3B1,* that clearly have clinical relevance in CLL and point to new biologic areas that will be pursued moving forward. All of these observations are important scientific areas of active, ongoing study, and readers are referred to several recent definitive reviews for further information on the basic biology of CLL. The biology and genetics covered within this chapter focus predominately on areas relevant to clinicians who care for patients with CLL.

IgV_H Mutational Status

Two seminal manuscripts in 1999 demonstrated that the IgV_H gene had undergone somatic mutation, indicating that the patient's CLL arose after this point in B-cell maturation, in 60% of CLL patients at diagnosis. In an attempt to identify surrogate genes associated with IgV_H-unmutated disease, ZAP-70 overexpression was identified. The majority of IgV_H-unmutated CLL cells have ZAP-70 expression and demonstrate evidence of syk activation and other essential BCR downstream activation signals after ligation of surface IgM (sIgM) that is related to overexpression of this protein. In contrast, virtually all IgV_H-mutated patients lack significant ZAP-70 expression and do not signal after ligation by sIgM, but can often weakly signal through other alternative BCRs. Thus, although gene expression profiling demonstrates all CLL cells to be most closely related to memory B cells, IgV_H-unmutated and -mutated CLL cells differ significantly with respect to their ability to transduce intracellular signals after sIgM ligation. A common repertoire of mutational changes among CLL patients has also been documented that differs significantly from that found in the normal adult B-cell repertoire. These studies have prompted the hypothesis that CLL may represent an antigen-driven disease. Targeting BBCR signaling based on this represents an attractive pharmacologic option that is being actively pursued in preclinical and clinical studies of several therapeutic agents directed against signaling pathways downstream of the BCR.

Defective Apoptosis

Since its initial description and early characterization, CLL has been considered a disease of slow accumulation of tumor cells caused by disrupted or defective apoptosis. Multiple studies have demonstrated that CLL cells overexpress several antiapoptotic proteins, including bcl-2, mcl-1, bak, and X-linked inactivator of apoptosis protein (XIAP), and have diminished expression of compensatory proapoptotic proteins such as bax. Overexpression of bcl-2 and mcl-1 and an increase of the ratio of these proteins to bax have correlated not only with disrupted apoptosis but also shortened OS and poor response to therapy. Why are these antiapoptotic genes overexpressed in vivo? Studies have demonstrated that CLL cells have constitutive activation of several anti-apoptotic transcription factors, including nuclear factor kappa-B (NFκB), nuclear factor of activated T cells (NFAT), and signal transducer and activator of transcription 3 (STAT3). Each of these transcription factors can influence one or more of the anti-apoptotic proteins that promote survival in vivo. The source of activation of these different transcription factors is not completely defined but may be partly attributable to autocrine and paracrine networks involving B-cell activation factor (BAFF), a proliferation inducing ligand (APRIL) vascular endothelial growth factor (VEGF), interleukin-4 (IL-4), and CD40. CLL cells are also maintained through contact with stromal cells (bone marrow [BM] and dendritic) and nurse similar cells through a complex interface of adhesion molecules and stromal survival factors such as stromal cell–derived factor (SDF). The importance of the in vivo environment to CLL survival is supported by the increase in apoptosis when CLL cells are cultured in vitro.

Genetic Abnormalities

Much of the advances in understanding the biology of acute leukemia have come from studying repetitively occurring cytogenetic abnormalities. Such detailed study of the genetics of CLL has been hindered by the inability to effectively induce proliferation of tumor cells for standard metaphase cytogenetic analysis and the poor response of CLL cells to B-cell mitogens. Nonetheless, several cytogenetic studies identified a variety of deletions, including del(11q22.3), del(17p13.1), del(13q14), and del(6q21-q23), as well as trisomy 12, as common abnormalities in CLL. The frequency of these abnormalities has been

further refined through the use of interphase cells using fluorescence in situ hybridization (FISH), which does not require isolation of dividing cells. These studies have demonstrated that del(13q14) is by far the most common cytogenetic abnormality in CLL followed by trisomy 12, del(11q22.3), del(17p13.1), and del(6q22.3). Stimulation studies with CpG oligonucleotides plus IL-4 or CD40 confirmed the prevalence of these abnormalities and identified unbalanced translocations not generally observed with traditional metaphase cytogenetics. The prognostic implications of these unbalanced translocations appear to be significant. Similarly, complexity of karyotype, as already appreciated in acute leukemia, appears to be a driving poor prognostic factor in CLL. Interestingly, balanced translocations, which are more frequently observed in ALL and AML, are generally not observed in CLL.

The presence of recurrent deletions in CLL suggests the possibility of unique tumor suppressor genes in these different regions. Extensive pursuit of such genes within the 13q14 region failed to identify a viable tumor suppressor gene candidate for many years. However, in 2002, Croce and colleagues identified miR15 and miR16, two noncoding microRNAs, in the deleted region of 13q14. Noncoding RNAs range in size from 21 to 25 nucleotides and represent a newly recognized class of gene products whose function is to silence genes through binding to the 3′-untranslated region of specific genes to inhibit translation. This same group later showed that mir16 regulates expression of bcl-2, which is overexpressed in CLL and other B-cell lymphoproliferative disorders. Multiple different studies have associated specific miR expression with rapid disease progression, fludarabine resistance, and poor prognosis. In addition, miR34a has been directly related to the adverse outcome associated with p53 dysfunction. Further study of miRs in CLL is under way to elucidate their full role in the pathogenesis and progression of CLL.

Recurring Mutations in Chronic Lymphocytic Leukemia

Until the advent of whole-exon and whole-genomic sequencing, CLL was not typically associated with recurring mutations early in the pathogenesis of the disease. Probably best characterized are p53 mutations, which occur in only 3% to 5% of patients at diagnosis, often in conjunction with deletion of the alternative allele (at 17p13.1 loci) that is associated with rapid disease progression and poor survival. With treatment and subsequent relapse, the frequency of p53 mutations continues to increase proportionately and is most common in patients with Richter transformation. Thus p53 mutations are considered by most to be a secondary abnormality in CLL associated with progression. Nonetheless, p53 mutations or deletions have significant impact on consideration of treatment of CLL, and the 2008 International Workshop on CLL (IWCLL) criteria recommended that patients with p53 mutations with deletions be treated in a different manner than other CLL patients. Although detailed studies of ATM mutations have followed by several groups, the impact of this abnormality is less well defined, in particular as it relates to treatment response. Other recurring mutations in CLL, including SF3B1, NOTCH1, MYD88, XPO1, and ERK1, have been described with recent whole-exon and -genome sequencing efforts. The impact of these new different mutations in the pathogenesis of CLL is under active investigation.

Immune and Microenvironmental Features

The importance of progressive immune suppression with progression of CLL has become appreciated in both human CLL and murine models of this disease. The absolute number of T cells and natural killer (NK) cells in CLL patients at diagnosis has been shown to predict OS. In particular, expansion of suppressive T-regulatory cells has been documented as patients come closer to the time of requiring therapy. The immunosuppressive effects observed in CLL lie predominately with the CLL clone, as recently demonstrated in very elegant work by the Gribben laboratory in human and mouse models of CLL. Similarly, the importance of microenvironment compartments of CLL such as lymph nodes and BM, where stromal cells provide proliferative signals as well as survival signals to protect from apoptosis, are recognized. Wiestner's group examined compartmental blood, node, and BM and demonstrated definitive differences in gene expression supporting this concept. Derived from this work are biomarkers of measurable chemokines responsible for T-cell recruitment to the microenvironment. Given the link of these stimuli to BCR signaling, these may be targetable by inhibitory molecules directed at kinases involved in this pathway.

CLINICAL MANIFESTATIONS

At diagnosis, CLL most often does not have clinical manifestations associated with the disease. For early stage CLL patients, the diagnosis is often identified as part of blood tests for evaluation of an unrelated problem such as infection, kidney stone, or preoperative assessment in which an elevated leukocyte count is noted with increased mature lymphocytes observed on the blood smear. For a much smaller subset of patients with CLL, presentation of disease occurs as a consequence of fatigue, weight loss, early satiety (from spleen enlargement), petechiae (from low platelets), or new palpable lymph nodes. Patients with symptomatic CLL at diagnosis represent only 15% of those seen, corresponding to the more indolent nature of this disease at diagnosis. With additional follow-up, the majority of CLL patients will eventually manifest symptoms of the disease that ultimately lead to the need for treatment. The most common symptoms with progression include increasing fatigue (as a consequence of anemia and cytokines from disease), lymph node and spleen size, worsening hematologic parameters (anemia and thrombocytopenia), and rarely infiltration of other organs (kidney, lung, pleural space, skin) that necessitates initiation of treatment to palliate symptoms. Unusual symptoms generally not associated with CLL progression are night sweats, fevers, and weight loss. These are generally suggestive of Richter transformation.

Separate from direct CLL progression, the disease is also immunosuppressive, and with more advanced disease, an increase in infections is generally observed. This represents a major morbidity of CLL and is a leading contribution to mortality associated with this disease. Other manifestations of immune suppression, including higher rate of secondary malignancies and autoimmune complications, are also increased in CLL (see box on Initial Evaluation of Young Patients With Chronic Lymphocytic Leukemia).

DIAGNOSIS AND LABORATORY MANIFESTATIONS

The diagnosis of CLL, as defined by the IWCLL 2008 criteria, requires an absolute malignant B-cell lymphocyte count of greater than 5000/μL. This differs from the previous NCI criteria that required a total lymphocyte count of 5000/μL and emphasizes the need to quantify the malignant B-cell clone in the new diagnostic criteria. Morphologically, the lymphocytes must appear mature with fewer than 55% prolymphocytes (Fig. 76-2, *A–E*). The BM aspirate smear must show greater than 30% of all nucleated cells to be lymphoid, or the BM core biopsy must show lymphoid infiltrates consistent with CLL (Fig. 76-2, *F* and *G*). The overall cellularity must be normocellular or hypercellular. Immunophenotyping must reveal a predominant B-cell monoclonal population coexpressing the B-cell markers CD19, CD20, and CD23 and the T-cell antigen CD5 in the absence of other pan-T cell markers (see later section).

Patients may present with tumor cells immunophenotypically consistent with CLL but have predominately lymph node disease without a peripheral B-cell lymphocyte count of 5000/μL despite BM involvement. Although these patients are considered to have small lymphocytic lymphoma (SLL) and not true CLL by the NCI criteria, the most recent World Health Organization (WHO) classification considers such SLL patients to have CLL, given the similar immunophenotypic features, genetic findings, natural history, and complications of these two diseases. The clinical management of SLL

Initial Evaluation of Young Patients With Chronic Lymphocytic Leukemia

Only 10% of patients diagnosed with CLL are younger than 50 years of age, and these patients often present a diagnostic and therapeutic dilemma to hematologists initially evaluating them. The great majority of patients diagnosed before the age of 50 years will have early-stage CLL with a slightly higher predisposition to a prior first-generation relative with this disease. Additionally, these patients are generally of a higher economic status or have chronic fatigue or medical illnesses for which they have been undergoing routine blood testing, leading to diagnosis of CLL. When the diagnosis of CLL is made, these younger patients have a more challenging time understanding how the disease will impact them. For patients with no symptoms referable to CLL, we generally discuss complications of the disease during the first visit and have a detailed discussion regarding assessment of genetic risk factors predisposing to early disease progression, including select interphase chromosomal abnormalities [del(17p13.1) and del(11q22.3)] and IgV_H mutational status (unmutated). During this time, it is important to counsel patients that identification of high-risk genomic features can actually increase anxiety because no treatment intervention is indicated in the absence of symptoms, regardless of genomic profile, outside of a clinical trial. In our experience, the great majority of patients desire this testing. Despite the potential benefit of allogeneic SCT in younger patients with CLL, we generally mention this only as one treatment option used in this disease and do not pursue consultation or tissue typing of patients or siblings until patients are truly symptomatic from their disease. We provide considerable discussion about the promising new kinase inhibitors coming forward in the treatment of CLL, analogous to how imatinib impacted treatment of CML. During the second visit 4 to 6 weeks later, we review the results of these prognostic factors and answer additional questions that have arisen. Ultimately, the majority of patients have low-risk disease, and knowing this allows patients to take partial control of their disease and move on with their lives. Serial assessment of the psychological well-being of patients with CLL during this first year is incredibly important. At no place during the evaluation do we refer to CLL as being a good or favorable leukemia. In our experience, the most common reason for dissatisfaction toward the initial hematology evaluation is lack of explanation of the disease process or the minimization of CLL as a "good leukemia to have."

For young patients presenting with other chronic medical problems who are asymptomatic from their CLL, we follow the approach outlined above. More commonly, these patients have fatigue, mild anemia, or other symptoms that could be referable to the CLL. Additionally, this group is more commonly overweight or obese. In either setting, it is important to first think like an internist and pursue other causes for symptoms potentially referable to CLL. In particular, encouragement of both weight loss and a fixed exercise plan should be encouraged for fatigue and often improve quality of life and in other medical comorbidities. It is very important to note that younger patients with CLL can often go a decade or more without therapy, and early treatment of this patient group in the absence of symptoms still offers no proven long-term advantage. For this reason, our group remains very conservative on starting therapy for young patients with CLL.

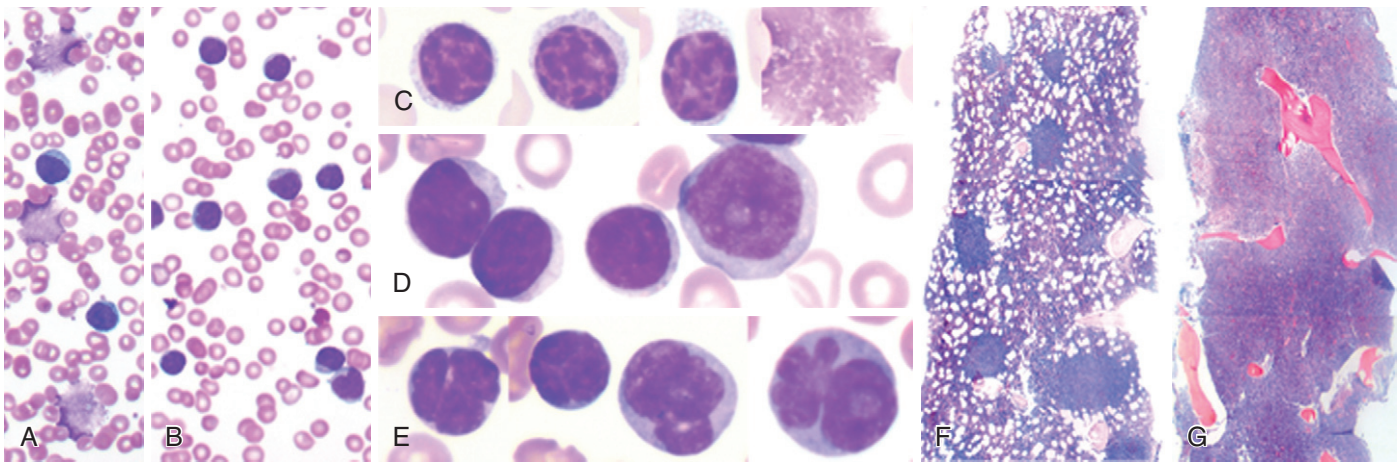

Figure 76-2 CHRONIC LYMPHOCYTIC LEUKEMIA (CLL). The peripheral blood smear **(A)** typically shows lymphocytosis and increased smudge cells as a result of the fragility of the CLL cells (see also smudge cell in **C,** *right side*). These can be avoided by making a preparation of blood and bovine serum albumin (22%) at a ratio of 11 drops of blood and 1 drop of albumin before preparing the slide **(B).** Cytologic features of CLL cells differ. Classic cells have a small nucleus with a "soccer ball" chromatin pattern **(C).** Some cases have increased large cells, or prolymphocytes, with more open chromatin and prominent "punched-out" nucleoli (**D;** prolymphocyte, *right side*). Other cases, sometimes referred to as "atypical," have clefted cells and large cells **(E).** The bone marrow can show nodular infiltrates of CLL cells **(F),** an interstitial infiltrate, or a diffuse infiltrate **(G).**

patients should be similar to CLL with respect to diagnostic testing and treatment. However, SLL patients may not be eligible for some clinical studies in CLL if those trials follow IWCLL 2008 criteria and mandate a peripheral malignant B-cell lymphocyte count of 5000/μL for study entry.

The recent increase in diagnostic blood testing for other B-cell lymphoid cancers has led to recognition of a precursor to CLL called monoclonal B-cell lymphocytosis (MBL). Patients with MBL have circulating peripheral B cells immunophenotypically consistent with CLL but do not have enlarged lymph nodes, a malignant lymphocyte count greater than 5000/μL, or cytopenias. The frequency of MBL increases with age; 0.3% of patients younger than the age of 40 years have MBL compared with 2.1% of 40- to 60-year-old patients and 5.2% of 60- to 90-year-old patients. The frequency of MBL in family members of patients with a first-degree relative with CLL is significantly higher in both young and older patients. With the new IWCLL 2008 definition of CLL requiring 5000/μL malignant B lymphocytes, more cases of MBL exist than in the past with many patients being downstaged from early CLL to MBL. This bears significant clinical relevance because it may allow patients to obtain health and life insurance easier. Similar to the relationship of monoclonal gammopathy of undetermined significance and multiple myeloma,

it appears that only a small proportion of patients with MBL develop overt CLL over time. Whereas genetic features such as IgV_H mutational status and cytogenetic abnormalities may predict for progression of CLL, it is unclear if these tests bear any relevance to predicting MBL progression. For this reason, we generally do not examine these tests in MBL patients.

LABORATORY MANIFESTATIONS

For many years, the diagnosis of CLL was made based on morphologic examination of the peripheral blood smear, which demonstrated mature lymphocytes with an abundance of smudge cells. Despite rigorous morphology, many diseases can mimic CLL in both appearance and clinical presentation, as summarized in Table 76-1, resulting in incorrect diagnoses. With the advent of new, more effective targeted therapies in CLL and other related diseases listed in Table 76-1, determining the correct diagnosis is of great importance. Flow cytometry, or immunophenotyping, has become a widely used diagnostic test that is currently performed in most reference pathology laboratories, and the use of flow cytometry is now the standard approach to establish the diagnosis of CLL (Fig. 76-3, for example). The diagnosis of CLL relies on immunophenotypic confirmation, and flow cytometry should therefore be performed on all CLL patients at diagnosis. CLL cells have a relatively consistent immunophenotype, which differentiates CLL from mantle cell lymphoma, hairy cell leukemia, follicular center cell lymphoma, splenic lymphoma with villous lymphocytes, and other indolent B-cell malignancies. Specifically, CLL cells express a variety of B-cell markers, including dim sIg, CD19, dim CD20 and CD23, as well as the pan T-cell marker CD5. κ or λ restriction is always present, establishing the presence of a clonal B-cell population, although sIg expression may be so dim that light chain restriction may be difficult to determine. In contrast, the presence of CD10, FMC7, or CD79b (all typically absent on CLL cells) or bright expression of CD11c, CD20, or CD25 (all typically dim on CLL cells) suggests an alternative low-grade B-cell lymphoproliferative malignancy. Expression of CD5 without CD23 suggests mantle cell lymphoma, and FISH for t(11;14) should be performed to exclude mantle cell lymphoma. Some genetic subsets of CLL are predisposed to variant antigen expression, particularly patients with trisomy 12. Repeating immunophenotyping after the initial diagnosis is not required unless there is a suspicion of transformation to a more aggressive histology or there is a need to assess BM response or antigen expression for an antibody directed therapeutic agent. Transformation of CLL (Fig. 76-4, *A* to *C*) to either prolymphocytic leukemia (PLL) or large cell lymphoma (Richter transformation) is often associated with immunophenotypic drift, where CD5 is lost and FMC7 expression is acquired. Additionally, expression of CD20 and surface immunoglobulin typically becomes brighter in PLL or Richter transformation. Although the morphologic appearance of prolymphocytes or large lymphoid cells in blood, BM or lymph nodes is typically adequate to make the diagnosis of transformation, flow cytometry may be useful in cases when morphologic findings are less clear.

Table 76-1 Diseases That Can Mimic Chronic Lymphocytic Leukemia

Follicular lymphoma
Mantle cell lymphoma
Monocytoid B-cell lymphoma or splenic lymphoma with villous lymphocytes
Hairy cell leukemia
Acute lymphoblastic leukemia
T-cell prolymphocytic leukemia
Large granular natural killer or T-cell leukemia

Patients with CLL often present with no symptoms, with the diagnosis being made as a consequence of asymptomatic enlarged lymph nodes or splenomegaly detected on physical examination or routine blood work done for another cause. Other patients present with symptoms of BM replacement (fatigue, dyspnea, or petechiae secondary to anemia and thrombocytopenia), symptomatic lymphadenopathy or hepatosplenomegaly, autoimmune complications (hemolytic anemia or idiopathic thrombocytopenic purpura), or B symptoms (fevers, night sweats, and weight loss). A small proportion of CLL patients will have pulmonary infiltrates at diagnosis that are representative of CLL involvement in some cases and active infection in others. Clearly, a wide spectrum of presentations exists for patients with CLL (see box on When Do I Consider a Transplant Evaluation in Chronic Lymphocytic Leukemia?).

In addition to blood and BM lymphocytosis, a few abnormal laboratory findings are commonly observed in CLL. Neutropenia, anemia, and thrombocytopenia can develop as a consequence of BM infiltration or myelosuppressive therapy administered to eliminate the leukemia. A positive direct antibody, or Coombs, test result is observed in approximately 10% to 25% of CLL patients at some time during the course of the disease. Similarly, autoimmune thrombocytopenia or neutropenia may be present, although other causes such as BM replacement or chemotherapy effect are much more common and should be excluded. Other nonhematologic autoimmune antibodies can rarely be present but do not appear to be more common than age-matched control patients without CLL. Pure red blood cell (RBC) aplasia can sometimes be observed with isolated anemia and absence of RBC precursor cells. Hypogammaglobulinemia is common in CLL and becomes more frequent and marked as the disease progresses. In contrast, hypercalcemia and markedly elevated lactate dehydrogenase (LDH) are not common in CLL and suggest Richter transformation.

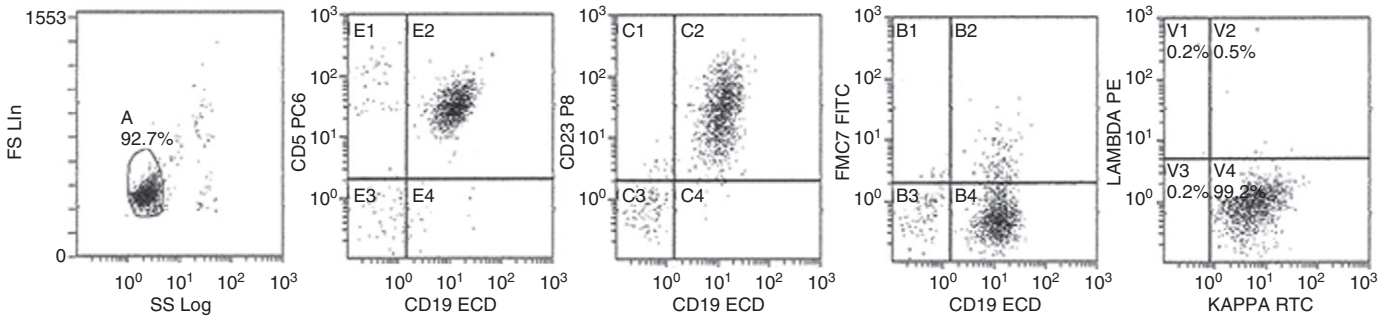

Figure 76-3 FLOW IMMUNOPHENOTYPING IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL). Flow data in a typical case of CLL. The phenotype is $CD19^+$ clonal B cells with κ light chain restriction (weak to moderately intense), with coexpression of CD5 and CD23, but lack of FMC-7. The cells were CD38 negative.

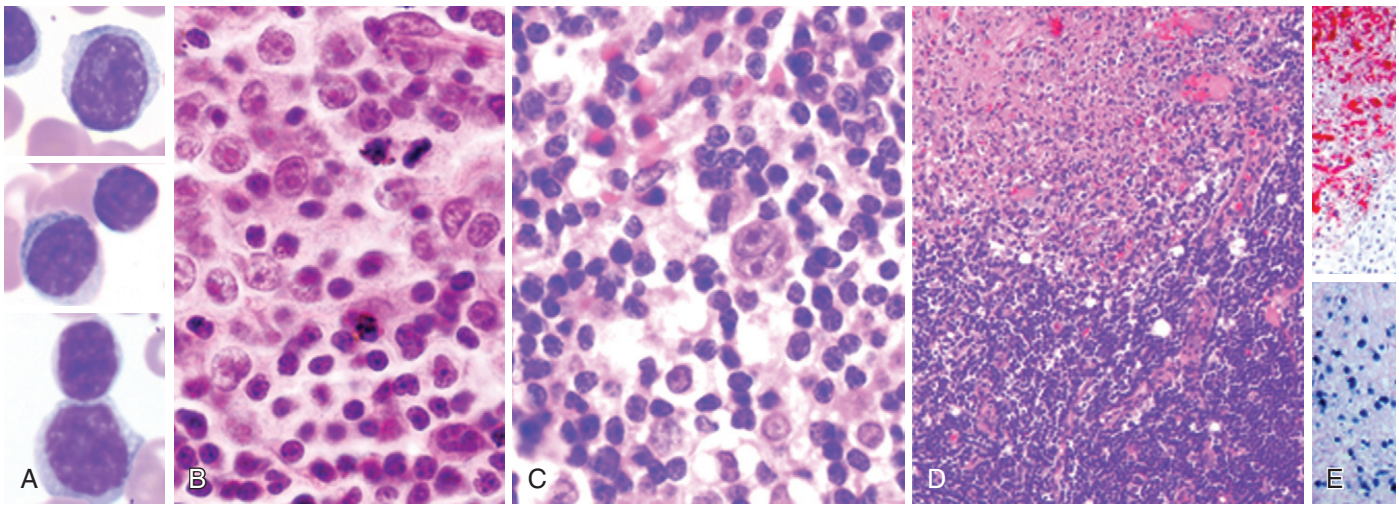

Figure 76-4 TRANSFORMATION IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL). Some patients of CLL develop increasing numbers of prolymphocytes **(A)** and a "prolymphocytic transformation." A Richter transformation is to a large-cell lymphoma (**B**; large cells, *upper left,* residual CLL, *lower right*). Occasionally, cases can transform to Hodgkin lymphoma (i.e., the Hodgkin variant of Richter syndrome) **(C).** With the use of fludarabine and other immunosuppressants, patient can also develop Epstein-Barr virus–related lymphadenopathies or lymphadenopathies with large areas of necrosis caused by herpes simplex virus (HSV). The case illustrated in **D** and **E** had both (**E;** *upper panel* shows an immunostain of HSV-1/2, and lower is EBER in situ hybridization).

When Do We Consider a Transplant Evaluation in Chronic Lymphocytic Leukemia?

With the introduction of nonmyeloablative stem cell transplantation, the morbidity and mortality associated with this therapy in CLL has decreased, and this option thereby has been extended to young and older patients alike. Additionally, extended follow-up in several transplant series has suggested that prolonged remissions can occur with this treatment approach, potentially providing the only curative therapeutic option for this disease. In general, we do not consider detailed discussion of transplant or referral for asymptomatic patients. When patients become symptomatic and require therapy for their CLL, we also consider if they would qualify for transplant. Approximately 50% of patients with CLL are 75 years of age or younger, have acceptable end-organ function, and lack comorbidities when symptomatic disease develops. It is this CLL patient group who may benefit from an allogeneic transplant consultation. Autologous transplant in CLL offers no opportunity for cure and is associated with treatment-related MDS/AML. For patients without del(17p13.1) attaining a complete remission to initial combination chemotherapy, we would never consider a consolidative SCT. However, for patients having only a partial response to combination therapy and who are likely to have only a short remission duration, consolidation transplant in the first partial remission should be strongly considered. Consolidation transplant after induction is generally pursued for patients with del(17p13.1) given the extreme poor outcome associated with this genetic group. For all patients relapsing after first therapy, we strongly recommend transplant evaluation and pursuit of this option after second treatment unless a complete remission is obtained again. For patients attaining a complete remission both to initial therapy and therapy at first relapse, remission duration can be prolonged and the allogeneic transplant can be delayed, particularly in the absence of high-risk genomic features. At the time of writing this chapter, introduction of kinase inhibitors appears to be altering the natural history of relapsed CLL similar to how imatinib influenced decisions of pursuing transplantation of CML in the 1990s. It is possible that the indication(s) for transplantation in CLL will change dramatically if these kinase inhibitors are eventually approved and alter long-term outcomes in CLL.

Table 76-2 Rai Staging System

Rai Stage at Diagnosis	Percent of Patients Never Requiring Chronic Lymphocytic Leukemia Therapy	Expected Survival in Months From Initial Diagnosis
0. Lymphocytosis >5 × 10^9/L only	59	150
1. Lymph node enlargement	21	101
2. Spleen or liver enlargement	23	71
3. Anemia with hemoglobin <11 g/dL	5	19
4. Thrombocytopenia <100 × 10^{12}/L	0	19

Adapted from Rai KR, Sawitsky A, Cronkite EP, et al. Clinical staging of chronic lymphocytic leukemia, *Blood* 46:219, 1975.

PROGNOSIS

Until recently, patients with CLL have been staged using either the Rai or Binet system. Both of these discriminate CLL by the sites of disease and degree of cytopenias induced by leukemia BM replacement. Patients can be categorized into three groups on the basis of these features. According to the modified Rai criteria, patients in the low-risk group (stage 0) have lymphocytosis without any other abnormality; patients in the intermediate-risk group (stages I and II) have, in addition to their lymphocytosis, enlarged lymph nodes, spleen, or liver; and patients in the high-risk group (stages III and IV) have anemia (hemoglobin <11.0 g/dL) or thrombocytopenia (platelets <100 × 10^9/L). The median survival times for the Rai low-, intermediate-, and high-risk groups are similar to those of Binet stages A, B, and C: 12+, 8, and 2 years (Table 76-2). For early-stage patients with CLL (Rai low and intermediate stage and Binet stages A and B), a significant range of time to developing symptoms of CLL exists. The lack of survival advantage with early treatment, the observation that a subset of CLL patients will never require therapy, and the varied

natural history of the disease have driven research efforts in CLL to identify specific biologic or clinical prognostic factors that predict time to progression.

Although lymphadenopathy is a common clinical feature of CLL and is incorporated into both major clinical staging systems, computed tomography (CT) scans are not commonly used to determine staging or to evaluate response to therapy outside of clinical trials. However, several studies have examined whether the incorporation of CT scans in initial staging or response evaluation may affect the ability to predict disease progression at diagnosis and assessment of clinical response to therapy. Although a few studies have suggested that these may help predict disease progression diagnosis, studies done serially at the time of treatment and for response show that CT scans generally do not impact assessment of response, progression-free survival (PFS), or OS. Additionally, CT scan identification of new nodal areas did not impact decisions for retreatment. Thus the use of CT scans in staging and response evaluation in CLL needs further study by well-designed, prospective clinical trials. However, CT scans should not be routinely incorporated in standard clinical use until their significance is evaluated within the context of such trials. Although CT scans have been the focus of greatest debate, the use of positron emission tomography (PET) should also be briefly discussed. Specifically, PET scans may be useful in detecting Richter transformation. In a single-institution study of 37 patients, PET scans identified 10 of 11 patients who had documented Richter transformation by tissue biopsy. However, nine patients had false-positive scans. Thus PET scans appear to be sensitive for Richter transformation, with a high negative predictive value, but specificity is poor. We generally use these studies to identify patients who warrant biopsy for Richter transformation and to localize where to biopsy.

With recent advances in the molecular biology of CLL, some prognostic factors such as BM infiltration pattern, which requires an invasive procedure at diagnosis, have not maintained their usefulness in predicting disease progression. Prognostic features outside of the traditional staging systems outlined above relative to daily practice are summarized below (Table 76-3).

Table 76-3 Evaluation of Chronic Lymphocytic Leukemia Patients at Diagnosis

History
B-symptom and fatigue assessment
Infectious history assessment
Occupational assessment for chemical exposure
Familial history of CLL and lymphoproliferative disorders
Preventive interventions for infections and secondary cancers
Physical Examination
LABORATORY ASSESSMENT
CBC with differential
Morphology assessment of lymphocytes
Chemistry, LFT enzymes, LDH
Flow cytometry assessment to confirm immunophenotype of CLL
Serum immunoglobulins
Serum β_2M levels
Interphase cytogenetics for del(17p13.1), del(11q22.3), del(13q14), del(6q21), and trisomy 12
IgV_H mutational analysis
Stimulated metaphase karyotype (if available)
Selected Tests Under Certain Circumstances
DAT, haptoglobin, reticulocyte count if anemia present
CT scan if unexplained abdominal pain or enlargement present
PET scan or biopsy (or both) if large nodal mass present
BM aspirate and biopsy if cytopenias present
Familial counseling if first-degree relative with CLL
Teaching
Varicella zoster identification instruction
Skin cancer identification
Disease education (Leukemia and Lymphoma Society, CLL Topics)

BM, Bone marrow; *CBC,* complete blood count; *CLL,* chronic lymphocytic leukemia; *CT,* computed tomography; *DAT,* direct antiglobulin test; *LDH,* lactate dehydrogenase; *LFT,* liver function test; *PET,* positron emission tomography.

Thymidine Kinase Activity and β_2-Microglobulin

Thymidine kinase is an enzyme involved in the salvage pathway of DNA synthesis and correlates with proliferative activity. Elevated thymidine kinase activity (TKA) has been observed to be predictive of early progression in a subgroup of untreated patients with smoldering CLL. β_2-Microglobulin (β_2M) is an extracellular protein component of the human leukocyte antigen (HLA) class I complex. β_2M has been shown to have significant prognostic relevance in lymphoma and multiple myeloma and correlates with disease burden in CLL. Hallek and colleagues examined 113 CLL and immunocytoma patients for β_2M levels and TKA and demonstrated that elevated TKA and β_2M both were independent predictors of shortened PFS. Keating et al confirmed the prognostic value of β_2M in 622 CLL patients, reporting that an elevated level was associated with a significantly shorter survival time for both untreated and previously treated patients. In this study, elevated β_2M was observed in patients with high tumor burden and extensive BM infiltration. In addition to disease progression, both β_2M and TKA have been associated with short duration of remission and inferior survival after treatment.

IgV_H Mutational Status

Although the malignant cell of CLL morphologically resembles a mature lymphocyte, genetic, immunologic, and phenotypic studies suggest that this cell is better designated as either a pregerminal or postgerminal B cell. Somatic mutations in the first and second complementarity-determining regions (CDR1 and CDR2) of the IgV_H genes are thought to occur in the germinal centers. Examination of IgV_H genes in patient cells suggests that there may be two subsets of CLL: leukemias whose cell of origin has successfully traversed the germinal center, resulting in the mutated IgV_H phenotype, and leukemias that are derived from naive B cells with the unmutated (germline) IgV_H sequence. Whereas approximately 60% of CLL patients have cells with mutated IgV_H genes (<98% identity to germline), the remaining patients have cells exhibiting unmutated IgV_H (≥98% sequence identity with germline), typical of pregerminal B cells. The prognostic significance of the absence of IgV_H gene mutations is substantial, with studies uniformly noting an inferior survival and high predisposition to requiring early treatment in this patient subset. A CLL Research Consortium study examined the impact of IgV_H mutation in 307 untreated CLL patients enrolled in a prospective tissue collection study. A total of 53% of these patients exhibited unmutated IgV_H genes, and this population had a significantly shorter median time to initial therapy (3.5 years) than those with mutated IgV_H (9.2 years; P <.001).

Because of the difficulties in determining IgV_H gene mutational status, researchers have sought surrogate markers for this parameter. Correlation between the absence of IgV_H gene mutations and elevated expression of the cell surface molecule CD38 on CLL cells was noted in one such report. In another work, ZAP-70 expression was shown to correlate with IgV_H gene mutational status. ZAP-70 is a T-cell receptor–associated tyrosine kinase that is aberrantly expressed in CLL cells, and ZAP-70 expression is generally found in patients with unmutated IgV_H but not in patients with mutated IgV_H. These two associated biomarkers appear to be linked directly to the difference in the behavior between these two genetic subtypes of CLL and are discussed independently. Other surrogate markers for the mutational status of the IgV_H gene have been reported, including methylation and subsequent silencing of TWIST2, a transcription factor that

negatively regulates p53. TWIST2 methylation and silencing are preferentially observed in IgV_H-mutated CLL cases. Elevated levels of lipoprotein lipase and related genes have been noted in patients with IgV_H-unmutated disease. Additionally, it has been reported that IgV_H-mutated CLL cells have long telomeres with low telomerase activity, but IgV_H-unmutated patients have short telomeres with high telomerase activity. The extreme shortening of telomeres and elevated telomerase activity are associated with both genetic instability and disrupted apoptosis in other diseases, suggesting that a similar process occurs in IgV_H-unmutated CLL cells. Finally, distinct gene and microRNA (miRNA) expression profiles have also been correlated with IgV_H gene mutational status.

CD38 Expression

Retrospective studies have shown that CD38 is an independent prognostic marker in CLL, demonstrating that high CD38 expression is associated with both a shorter time from diagnosis to treatment and inferior survival. CD38 functional studies using CD31 and plexin B1 transfected fibroblasts have provided a biologic explanation for this observation. CD38 interaction with its ligand, CD31, in the presence of IL-2 results in upregulation of the survival receptor CD100 exclusively on proliferating CLL cells. This occurs with concomitant downmodulation of CD72, a negative regulator of immune response. The interaction between CD38 and CD100 on CLL cells and CD31 and plexin B1, respectively, on transfected fibroblasts results in enhanced survival and growth of CLL cells. Furthermore, the presence of nurse-like cells in CLL patients expressing high levels of CD31 and plexin B1 corroborates the interplay of CD38 and CD31 and provides further evidence of activation of circulating CD38-positive CLL cells by the microenvironment. This finding also may explain the aggressive nature of these CLL clones.

ZAP-70

ZAP-70 expression was identified as another surrogate marker for IgV_H gene mutational status by a cDNA microarray analysis of untreated CLL patients. Functional studies in ZAP-70–positive cases have shown that BCR ligation leads to increased phosphorylation of cytosolic proteins (Syk, BLNK, PLCγ), calcium mobilization, degradation of IκB, and ultimately NFκB target gene activation. Despite clear data showing that ZAP-70 is a prognostic factor, the reproducibility of this assay across laboratories has been problematic. Inconsistent measurement of ZAP-70 may be the cause because ZAP-70 is a labile protein, and laboratories have used different methods and reagents. Given the challenges of measuring ZAP-70 protein accurately, others have attempted to identify alternative markers or more stable readouts of ZAP-70 expression. For example, methylation of select regions in the proximal 5′ region of the ZAP-70 gene has been shown to correlate closely with expression of ZAP-70 and influence treatment outcome. Overall, despite the apparent usefulness of ZAP-70 in research laboratories for discriminating CLL patients at high risk for progression, this test currently is not useful for clinical practice.

Chromosomal Aberrations

Conventional metaphase cytogenetics can identify chromosomal aberrations in only 20% to 50% of CLL cases because of the low in vitro mitotic activity of CLL cells. Abnormalities noted in descending frequency of occurrence include trisomy 12; deletions at 13q14; structural aberrations of 14q32; and deletions of 11q, 17p, and 6q. In addition, a complex karyotype (three or more abnormalities) occurs in approximately 15% of patients and predicts for rapid disease progression, Richter transformation, and inferior survival. A recent study showed that the use of CD40L or the combination of IL-2 and CpG stimulation revealed translocations in 33 of 96 patients (34%). These translocations were both balanced and unbalanced, occurring in 13q14, 11(q21q25), 14q32, or regions also seen in lymphomas such as 1(p32p36), 1(q21q25), 2(p11p13), 6(p11p12), 6(p21p25), and 18q21. These data define a new prognostic subgroup of patients with significantly shorter median time from diagnosis to requiring therapy (24 vs. 106 months) and OS (94 vs. 346 months) compared with those without translocations. The frequency of these translocations in untreated patients was less common, suggesting that these accumulate with disease progression. Although of interest, these findings require additional prospective validation before being used as a standard prognostic tool for CLL patients.

Given the limitation of standard or stimulated karyotype analysis, interphase FISH has become the state-of-the-art technique for accurately distinguishing genetic subtypes of CLL. The largest study of interphase FISH resulted in improved sensitivity to detect partial trisomies (12q12, 3q27, 8q24), deletions (13q14, 11q22-23, 6q21, 6q27, 17p13), and translocations (band 14q32) in more than 80% of all cases. In a large study of 325 patients by Dohner and colleagues, a hierarchical model consisting of five genetic subgroups was constructed on the basis of regression analysis of CLL patients with chromosomal aberrations. Patients with a 17p deletion had the shortest median survival time (32 months) and the shortest treatment-free interval (TFI, months); patients with an 11q deletion followed closely with 79 months and 13 months, respectively. Whereas the favorable 13q14 deletion group had a long TFI of 92 months and a median survival of 133 months, the group without detectable chromosomal anomalies and those with trisomy 12 fell into the intermediate group with median survival of 111 and 114 months, respectively, and TFI of 33 and 49 months, respectively. According to this pivotal study, CLL patients are prioritized in a hierarchical order (deletion 17p13 > deletion 11q22-q23 > trisomy 12 > no aberration > deletion 13q14). The hierarchical model of cytogenetic abnormalities in predicting disease progression by FISH has been further confirmed by other studies. Of interest, patients with high-risk interphase cytogenetic abnormalities or other complex abnormalities are almost always found to have IgVH-unmutated CLL. The impact of high-risk interphase cytogenetics relative to disease progression, outside of its association with IgVH-unmutated CLL, in at least one study had less impact on outcome.

Preliminary Prospective Validation of New Biomarkers From the German Chronic Lymphocytic Leukemia Study Group

The CLL-1 Study of the German CLL Study Group (GCLLSG) is a randomized phase III study of early treatment with fludarabine versus observation in newly diagnosed CLL patients. Risk of progression is determined on the basis of lymphocyte-doubling time, thymidine kinase, and diffuse BM pattern. Differing from other early-intervention studies, patients with disease that meet one or more of the NCI 96 criteria (i.e., lymphocyte-doubling times <1 year) may enroll. Accompanying this study is the plan to assess interphase FISH, IgV_H mutations, and β_2M level to determine their independent prognostic significance compared with other variables. If shown to be of prospective importance relative to predicting early treatment progression, these laboratory tests would be incorporated into subsequent risk stratification criteria. IgV_H-unmutated disease represented 41% of patients at diagnosis. Patients with IgV_H-unmutated disease assigned to observation had a median time to symptomatic disease of only 2 years. High-risk karyotypes were present in 15% of cases, with the great majority being IgV_H unmutated. A preliminary analysis of the first 340 patients randomized to observation suggested that IgV_H-unmutated disease, high-risk interphase FISH, thymidine kinase, and lymphocyte-doubling time correlated with time to first treatment. Publication of these large prospective new prognostic factors will be important to determining the risk of CLL progression (see box on How Should Staging and Biomarkers Be Used for Treatment Decisions in Chronic Lymphocytic Leukemia Patients?).

How Should Staging and Biomarkers Be Used for Treatment Decisions in Chronic Lymphocytic Leukemia Patients?

Our understanding of the biology of CLL has improved dramatically, and many relevant biomarkers are now becoming useful for predicting when CLL will clinically progress. However, no study to date has demonstrated that earlier treatment will alter the natural history of the patient in even the higher risk groups with high progression rates. Therefore, at the present time, the use of staging and predictive biomarkers should be used only to provide patients with information relative to the expected course of their disease. Outside of a clinical trial, these results should never be used to initiate therapy in patients with asymptomatic disease and no indication for treatment. Before performing predictive tests, a detailed discussion of how these tests will be used with the patient should occur and the option of not performing them should be provided. In a subset of patients, significant anxiety can be produced by identifying high-risk features for which observation, without therapeutic intervention, remains the standard of care. Table 76-3 provides an example of the initial evaluation provided by our group when seeing a newly diagnosed patient. Because lymphocyte-doubling time is a prognostic feature in the progression of CLL, our approach is to follow patients every 3 months during the first year; if little change in clinical or laboratory parameters occurs at this point, we extend this time period to every 6 months in the absence of new complaints.

TREATMENT

Initiation of Treatment of Newly Diagnosed or Previously Untreated Patients

Many patients are incidentally diagnosed with CLL on routine complete blood count examination and are asymptomatic with a normal hemoglobin and platelet count at time of initial diagnosis. Expectant observation without therapy is the standard practice for such asymptomatic patients, and patients receive treatment only when their disease progresses. This practice is based on several studies that failed to show an improvement in OS when early therapeutic intervention with chlorambucil therapy was administered to asymptomatic patients. A meta-analysis of 2048 patients in six trials demonstrated no difference in death rate between patients who were randomized to early therapy (42.6%) and those with treatment deferred (41.6%). Thus patients with asymptomatic or early-stage disease derive no therapeutic benefit from early alkylating agent therapy. However, in these studies, chlorambucil was administered as initial therapy, and chlorambucil achieves complete response (CR) in few patients. The past decade has seen the development of more effective treatment regimens combining monoclonal antibody therapy with purine analogs (chemoimmunotherapy), which are able to achieve CR in a majority of previously untreated patients, and the increasing use of new molecular markers to risk stratify newly diagnosed CLL patients. Furthermore, it is now well established that CLL undergoes genetic clonal evolution over time with greater frequency in IgV_H-unmutated CLL, resulting in increasing resistance to therapy in this patient population. Thus the issue of early treatment needs to be reconsidered, particularly in patients with high-risk biological or molecular markers predicting a poor long-term prognosis, such as IgV_H-unmutated disease. Ongoing efforts within the GCLLSG will hopefully determine whether early intervention with chemoimmunotherapy regimens will improve long-term survival in patients with high-risk CLL.

To establish uniform clinical practice standards and ensure reproducible eligibility criteria for entrance into clinical studies, the IWCLL established guidelines for initiation of treatment. Indications to begin therapy included non-autoimmune cytopenias (Rai stage III and IV), bulky or symptomatic lymphadenopathy or hepatosplenomegaly, disease-related B symptoms or fatigue, extreme lymphocytosis (>300 × 109/L) or a rapid lymphocyte-doubling time, and autoimmune hemolytic anemia (AIHA) or thrombocytopenia not controlled with steroids. It is imperative to determine if a patient's symptoms are attributable to CLL or a comorbid medical condition because constitutional symptoms such as fatigue are nonspecific and can be caused by many etiologies in elderly patients with comorbid illnesses. In addition to the official IWCLL 2008 criteria for therapy, an increasing frequency of infections and slowly progressive anemia are other indications that can aid the practicing physician in deciding when to initiate therapy in patients with CLL. A summary of the IWCLL 2008 guidelines for treatment is provided in Table 76-4 with some minimal modifications used by our group.

Table 76-4 Modified Indications for Treatment of Chronic Lymphocytic Leukemia

Grade 2 or greater fatigue limiting life activities
B symptoms persisting for ≥2 weeks
Lymph nodes >10 cm or progressively enlarging lymph nodes causing symptoms
Spleen or liver with progressive enlargement or causing symptoms
Anemia (hemoglobin <11 g/dL) referable to CLL
Thrombocytopenia (platelets $<100 \times 10^{12}$/L) referable to CLL or ITP poorly responsive to traditional therapy
WBC count $>300 \times 10^{9}$/L on two occasions 2 weeks apart if no alternative comorbid diseases increase morbidity of treatment
Severe paraneoplastic (e.g., insect hypersensitivity, vasculitis, myositis) process related to CLL not responsive to traditional therapies

AIHA, Autoimmune hemolytic anemia; *CLL,* chronic lymphocytic leukemia; *ITP,* idiopathic thrombocytopenic purpura; *WBC,* white blood cell.

A useful paradigm for clinical practice is to institute treatment in CLL only for cytopenias or directly referable symptoms. When treatment is necessary, a variety of agents have been examined in clinical trials (outlined below). Previously identified biomarkers are used in selecting the initial treatment for CLL, and the utility of more recently identified biomarkers currently are under study by several groups. In general, patients with del(17p13.1) do not respond well to traditional therapy and should be considered for more aggressive interventions such as allogeneic stem cell transplantation (SCT) as part of initial therapy. Patients with del(11q22.3) appear to have improved outcome with hyperfractionated cyclophosphamide as part of the FCR (fludarabine–cyclophosphamide–rituximab) regimen. Additionally, several studies have shown that CLL patients older than 70 years of age or who have multiple comorbid illnesses do not benefit from fludarabine-containing regimens, and this needs to be factored into treatment algorithms. Below, we summarize the findings of clinical studies of different treatments for CLL; where such data exist, we integrate genomic biomarkers as well as clinical features, including age and comorbid illnesses. Different therapies are outlined below with attention to details related to their initial use in previously untreated CLL. Because many of these regimens were also developed in relapsed CLL, these data are also reviewed and later referred to in the section Treatment of Patients With Relapsed Chronic Lymphocytic Leukemia.

Cytotoxic Chemotherapy

Alkylating Agents

Chlorambucil and other alkylating agents have served as first-line therapy for CLL for many decades, and chlorambucil is still given as first-line therapy for some patients, particularly older patients and patients who cannot tolerate purine analog therapy. Chlorambucil is generally administered as a single pulse dose 40 mg/m^2 orally (PO) every 28 days with or without concomitant steroid therapy, although alternative dosing schedules are used, particularly in Europe. Chlorambucil is typically given without steroid therapy because the addition of steroids to alkylating agent therapy has not been shown to

improve survival. Although a high-dose continuous dosing schedule of 15 mg/day PO has been evaluated in several large European studies and led to results superior to those of pulse therapy, high-dose therapy is associated with greater myelosuppression and frequently requires dose reduction, particularly in older or more fragile patients in whom chlorambucil is typically considered. Although high-dose therapy may be more effective if maximal cytoreduction is desired, the less intensive pulse dosing schedule should generally be used outside the setting of a clinical study. Because most studies of alkylating agent therapy predated widespread use of cytogenetic and biological risk factors, data on the effect of biomarkers on response to chlorambucil are limited. However, the existing data indicate that patients with del(11q22.3) or del(17p13.1) have a lower response rate and a shorter remission duration to chlorambucil compared with patients without these abnormalities. The primary advantages of chlorambucil are its well-established toxicity profile and its low cost; its primary disadvantages are its low CR rate, even in previously untreated patients, and the small possibility of developing myelodysplasia with extended therapy. Although not typically given as a single agent to younger patients, its use should be considered in older patients and other patients who may not tolerate fludarabine therapy. Given the benefit of the chimeric monoclonal anti-CD20 antibody rituximab as part of chemoimmunotherapy regimens with fludarabine, several pilot studies have been performed combining chlorambucil with rituximab. These have shown promising results and favorable toxicity profile, prompting an ongoing phase III study of this combination, compared with single-agent chlorambucil, by the GCLLSG. This phase III study also includes an experimental arm combining chlorambucil with the novel type II monoclonal anti-CD20 antibody obinutuzumab (GA-101). A similar phase III study comparing the combination of chlorambucil and the fully human anti-CD20 antibody ofatumumab has completed accrual. (Both obinutuzumab and ofatumumab are discussed later in this chapter.)

Bendamustine

Although typically classified as a bifunctional alkylator, bendamustine has an uncertain mechanism of action. Although the drug predominately promotes cytotoxicity by inducing DNA damage and reactive oxygen species, in NCI60 cell line studies, bendamustine displayed a distinct pattern of activity unrelated to other DNA-alkylating agents but closest to melphalan. Unlike other alkylating agents, bendamustine activates a base excision DNA repair pathway rather than an alkyltransferase DNA repair mechanism. Studies of bendamustine in a variety of solid tumors, non-Hodgkin lymphoma (NHL), multiple myeloma, Hodgkin disease, and CLL have shown single agent activity. Bendamustine has been widely used in Eastern Germany and several European countries for decades and was approved by the U.S. Food and Drug Administration (FDA) for treatment of CLL in 2008. This was based on a well-controlled, randomized phase III study comparing bendamustine 100 mg/m^2 intravenous (IV) on days 1 and 2 with chlorambucil 0.8 mg/kg PO on days 1 and 15 every 4 weeks for 6 cycles. A total of 319 patients were enrolled with an overall response rate (ORR) of 68% and 31% CR with bendamustine versus 31% ORR and 2% CR with chlorambucil treatment (P <.0001). The median PFS was significantly better (P <.0001) with bendamustine (21.6 vs. 8.3 months) than chlorambucil. Grade 3/4 hematologic toxicity and severe infections (grades 3-4) occurred more commonly with bendamustine. Overall, this study and others that have followed showed that bendamustine is well tolerated in young and old CLL patients. This agent has been effectively combined with rituximab and is currently being pursued as a phase III study by the GCLLSG.

Combination Chemotherapy With Alkylating Agents

A variety of trials combining alkylating agents and other cytotoxic agents have been performed. A phase III Eastern Cooperative Oncology Group (ECOG) study of chlorambucil and prednisone (CP) with or without vincristine (CVP) demonstrated no benefit in PFS for the CVP arm. The French CLL group showed that a modified CHOP (cyclophosphamide, Adriamycin, vincristine, prednisone) regimen was superior to CVP and achieved similar results as fludarabine monotherapy. A meta-analysis compared alkylating agent-based combination regimens with a single-agent regimen based on an alkylating agent and demonstrated no survival benefit. Given that alkylating agent–based combination regimens are associated with more toxicity and show no benefit over fludarabine-based therapy, our approach is to use the latter for most patients. Only in rare cases of de novo CLL do we consider alkylating agent–based combination therapy (i.e., a young patient without comorbid illnesses who has fludarabine toxicity that prohibits further use or a patient with renal failure who cannot receive fludarabine). In the relapse setting, although salvage lymphoma regimens such as CHOP-R, RICE, and ESHAP-R are used to treat CLL, clinical studies of these regimens in CLL are lacking, and the utility of these regimens is undefined.

Purine Analogs

The introduction of purine analogs in the 1980s by Grever and later Keating revolutionized CLL therapy, and fludarabine has demonstrated significant clinical efficacy in both relapsed and previously untreated CLL. Pentostatin was the first nucleoside analog that demonstrated clinical activity in CLL and related B-cell lymphoproliferative disorders; however, subsequent phase II studies showed modest activity, limiting further trials of this agent. Given its more favorable myelosuppression profile compared with other nucleoside analogs, pentostatin has been combined with other agents and shown favorable clinical activity and toxicity in selected populations. Two other nucleoside analogs, fludarabine and cladribine, were subsequently found to be clinically active in CLL. Phase II to III studies of cladribine monotherapy achieved similar clinical responses as alkylating agent–based treatment but were associated with more cytopenias and immune suppression. The FDA approved fludarabine for the treatment of CLL, and thus most studies of purine analog–based therapy in CLL have focused on fludarabine. The remainder of this section focuses predominately on clinical trials of fludarabine.

Fludarabine was initially approved by the FDA for alkylating agent–resistant CLL in 1991 based on two phase II studies demonstrating a high response rate to fludarabine in this patient subset, prompting several additional trials of fludarabine as monotherapy in relapsed and previously untreated CLL. After the observation of high response rates and a 33% CR rate in previously untreated CLL by Keating and colleagues, several large prospective randomized studies in previously untreated CLL patients compared alkylating agent–based regimens with fludarabine. These studies collectively established fludarabine as an accepted standard first-line therapy for CLL based on improved response rates and PFS. These studies are summarized in Table 76-4. A multicenter European study randomized 196 evaluable patients to fludarabine or cyclophosphamide, doxorubicin, and prednisone (CAP). The ORR favored fludarabine (60% vs. 44%), and this benefit was observed in both relapsed (n = 96; 48% vs. 27%) and previously untreated (n = 100; 71% vs. 60%) patients, although the difference was not statistically significant in the untreated group. Fludarabine achieved a longer median duration of response than did CAP, with a tendency toward longer OS in previously untreated patients. A randomized, multicenter American study confirmed these findings in 509 previously untreated CLL patients. Patients were randomized to receive fludarabine 25 mg/m^2 IV daily for 5 days every 28 days, chlorambucil 40 mg/m^2 PO every 28 days, or fludarabine 20 mg/m^2 daily for 5 days and chlorambucil 20 mg/m^2 PO every 28 days, for up to 12 cycles. Patients who failed to respond or relapsed were allowed to cross over to the other arm. The combination arm was closed because of excessive toxicity. Fludarabine achieved a superior CR rate, ORR, median duration of remission, and median duration of PFS (20%, 63%, 25 months, 20 months,

respectively) than did chlorambucil (4%, 37%, 14 months, 14 months, respectively). However, there was no statistically significant difference in OS even at 10 years of follow-up (66 vs. 56 months), possibly because of the crossover design. A multicenter French study randomized 938 patients with previously untreated Binet stage B and C CLL to fludarabine, CHOP, or CAP. Although fludarabine achieved better response rates than CAP, OS (67-70 months) was identical in all three treatment groups. Thus single-agent fludarabine achieves superior response rates and duration of PFS to alkylating agent–based regimens. The impact of prognostic factors on response rates and duration of PFS to fludarabine was recently examined; patients with high-risk cytogenetic abnormalities, including del(11q22.3) and del(17p13.1), have significantly shorter PFS in response to fludarabine-based therapy than patients with other cytogenetic abnormalities.

However, the benefit of fludarabine does not apply to patients older than the age of 65 years. A phase III trial by the GCLLSG randomized 193 previously untreated CLL patients older than 65 years to fludarabine 25 mg/m^2 IV for 5 days every 28 days for 6 cycles or chlorambucil 0.4 to 0.8 mg/kg PO every 15 days for 12 months. Fludarabine achieved higher OR (72% vs. 51%) and CR rates (7% vs. 0%) and longer time to treatment failure (19 vs. 18 months). However, PFS was similar in both arms (19 months vs. 18 months), and OS was 46 months for fludarabine compared with 64 months for chlorambucil arm ($P = .15$). Thus the results achieved in younger patients do not necessarily apply to older patients with comorbid diseases or who otherwise cannot tolerate more aggressive therapies.

Combining Fludarabine With Alkylating Agent Therapy

Fludarabine was combined with cyclophosphamide (Flu/Cy) in three randomized phase III studies, based on two promising pilot studies in previously untreated CLL patients, with the goal of improving response rates and hopefully long-term survival. The GCLLSG randomized 375 previously untreated patients (age younger than 65 years) to standard fludarabine or Flu/Cy (fludarabine 30 mg/m^2 IV and cyclophosphamide 250 mg/m^2 IV daily for 3 days) every 28 days for 6 cycles. The ORR (94% vs. 83%), CR rate (24% vs. 7%), median PFS (48 vs. 20 months), and duration of treatment-free survival (37 vs. 25 months) all favored Flu/Cy, although there were more patients with cytopenias in the combination arm. Furthermore, no difference in OS was observed. EGOG randomized 278 patients to single-agent fludarabine or fludarabine 25 mg/m^2 on days 1 to 5, cyclophosphamide 600 mg/m^2 on day 1, and granulocyte colony-stimulating factor (G-CSF) support every 28 days for 6 cycles. Flu/Cy therapy achieved a superior ORR (74% vs. 59%), rates of CR (23% vs. 5%), and duration of PFS (32 vs. 19 months), although no OS advantage was observed. Most recently, the United Kingdom LRF CLL4 study randomized 777 patients to oral chlorambucil, fludarabine, or Flu/Cy. Patients randomized to Flu/Cy enjoyed superior ORR, CR rates, and 5-year PFS rates (94%, 39%, and 33%, respectively) to patients who received chlorambucil (72%, 7%, and 9%, respectively) or fludarabine (80%, 15%, and 14%, respectively).

Thus three large, prospective, randomized, multicenter studies in the United States and Europe have clearly demonstrated that Flu/Cy therapy is associated with better response rates and duration of PFS than single-agent fludarabine. However, no OS advantage for upfront Flu/Cy has been observed to date. Although toxicity has generally been manageable, greater hematologic toxicity has been observed with Flu/Cy. Additionally, patients older than 65 or 70 years, who make up the majority of CLL patients receiving initial therapy in clinical practice, have either been excluded or minimally represented in these trials. Further studies are needed to determine if Flu/Cy is as well tolerated and active in older patients as it is in younger patients. Finally, of these patients, long-term follow-up is required to determine the duration of remission, OS, and the incidence of potential late complications such as therapy-related myeloid neoplasia (tr-MN) to fully assess the utility of the Flu/Cy regimen. Indeed, the US Intergroup study of FC versus F suggested an increased risk of tr-MN in the FC arm. Examination of outcome by cytogenetic risk groups showed that patients with high-risk cytogenetic abnormalities, including del(11q22.3) and del(17p13.1), had a significantly shorter remission than patients in the groups with good- or intermediate-risk cytogenetic findings. Thus the addition of alkylating agents to fludarabine does not appear to alter the poor prognosis associated with high-risk cytogenetic abnormalities.

Rituximab

Rituximab is a chimeric murine monoclonal antibody that targets the CD20 antigen on the surface of normal and malignant B lymphocytes, and is the best studied and most widely used monoclonal antibody for the treatment of CLL and B-NHL. CD20, a calcium channel that interacts with the BCR complex, is an ideal target, because CD20 is expressed in 90% to 100% of CLL and B-NHL and is only minimally internalized or shed. Rituximab induces antibody-dependent cellular cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC), activates caspase 3, and induces apoptosis in CLL and B-NHL cells. Thus multiple mechanisms of action likely contribute to rituximab's effectiveness in CLL.

In phase I clinical studies in indolent B-NHL rituximab, 375 mg/m^2 IV was administered weekly for four doses, although the dose and length of treatment were empirically determined. The pivotal phase II trial of rituximab was pursued in 166 patients with relapsed or refractory indolent B-NHL, including SLL. Although an ORR of 60% was achieved in indolent follicle center B-NHL, only four of 30 patients (13%) with SLL/CLL responded. Similarly, disappointing results were obtained in several other small studies. Responses in each of these studies were predominately in the blood and nodal compartment with little improvement in BM disease. In contrast, two trials in which higher doses of rituximab weekly (≤2250 mg/m^2 per dose) or in which rituximab was administered thrice weekly (at 375 mg/m^2) to relapsed CLL patients showed improved response rate with response duration approaching that achieved in follicular B-NHL in prior trials. These studies established a role for single-agent rituximab in patients with relapsed CLL and lead to combination with other agents.

In contrast to studies in relapsed CLL, weekly single-agent rituximab demonstrated greater clinical efficacy when given to patients with previously untreated SLL/CLL. Forty-four previously untreated patients with SLL/CLL received 4-weekly doses of rituximab 375 mg/m^2; the ORR after the first course of rituximab was 51% (CR 4%). Twenty-eight patients with stable or responsive disease received additional 4-week courses of rituximab every 6 months for up to 4 cycles. However, there was only a modest increase in ORR (58%) and CR rates (9%), and the median duration of PFS of 19 months was shorter than the 36- to 40-month median duration of PFS reported by the same investigators using the same regimen in previously untreated patients with follicle center B-NHL. Nonetheless, this response duration compared favorably with the response duration achieved with fludarabine in the upfront setting, suggesting that rituximab is active and may have a role in the upfront therapy of SLL/CLL.

Rituximab is selective for the B-cell antigen CD20 and therefore has a relatively favorable toxicity profile. Toxicity associated with infusion of this agent commonly occurs with the first infusion of rituximab and may be greater in patients with CLL compared with patients with NHL. These symptoms generally include fever, rigors, transient hypoxemia, dyspnea, and hypotension, which are partly caused by an inflammatory cytokine release syndrome. Although poorly understood, CLL patients with platelet counts less than 50 × 1012/L may experience transient, severe thrombocytopenia associated with this infusional toxicity and may require platelet transfusions with the first one or two doses of rituximab. Patients with preexisting thrombocytopenia should therefore have a posttherapy platelet count after the first one or two doses of rituximab. Another uncommon but potentially severe toxicity is a tumor lysis syndrome, which is generally observed in patients with a high circulating peripheral

lymphocyte count with CLL variants. Such patients should receive prophylactic allopurinol, hydration, and careful observation, and inpatient monitoring and administration of rituximab can be considered for the highest risk patients. Patients who develop tumor lysis syndrome after the first dose of rituximab can safely receive subsequent doses, especially after the number of circulating CLL cells is reduced. Other rare toxicities with rituximab therapy include delayed neutropenia, hepatitis B reactivation, skin toxicity, interstitial pneumonitis, serum sickness, and progressive multifocal encephalopathy. Patients with prior hepatitis B exposure, as indicated by positive serologies, should receive rituximab only if viral load testing indicates no active disease. Such patients should undergo regular viral load monitoring during and after completion of rituximab therapy, and prophylactic antiviral therapy may be considered to reduce the likelihood of viral reactivation. Patients who develop profound neutropenia, pulmonary, or skin toxicity with rituximab should not be challenged with repeated dosing. In general, rituximab is a very well-tolerated therapy, making it ideal for use in combination with other agents in patients with CLL.

Phase II Studies of Rituximab Chemoimmunotherapy

Given its activity and toxicity profile, rituximab has been combined with cytotoxic chemotherapy in the treatment of CLL, and clinical trials have examined several such chemoimmunotherapy regimens. Studies of chemoimmunotherapy in CLL have focused primarily on fludarabine-based combinations because of the established role of fludarabine therapy in this disease. The approval of bendamustine and potentially an alternative mechanism compared with alkylator agents and fludarabine has led to combination therapy of bendamustine with rituximab. Finally, given the recent recognition that elderly patients do not benefit from fludarabine-containing regimens, several trials have also combined rituximab with chlorambucil with promising results. Alternative regimens including FCR–mitoxantrone (FCR-M) and pentostatin, rituximab, and cyclophosphamide (PCR) have been published and used in CLL but are unlikely to be building blocks for improvement in CLL therapy in the future and are therefore not described below.

Fludarabine and Rituximab

The CALGB 9712 study randomized 104 previously untreated CLL patients to sequential or concurrent fludarabine and rituximab (FR) therapy. Patients received standard fludarabine 25 mg/m^2 days 1 to 5 every 4 weeks for 6 cycles with or without concurrent rituximab 375 mg/m^2 on day 1 of each cycle with an additional dose on day 4 of cycle 1. Patients in both arms received rituximab 375 mg/m^2 weekly for four doses beginning 2 months after completion of fludarabine; thus patients in the concurrent arm received 11 total doses of rituximab compared with four in the sequential arm. Patients receiving concurrent FR therapy enjoyed a superior CR rate (47% vs. 28%) and ORR (90% vs. 77%) to patients in the sequential arm. Retrospective comparison to a fludarabine only–containing treatment study performed previously by CALGB demonstrated improved PFS and OS compared with fludarabine treatment. Analysis of prognostic cytogenetic abnormalities demonstrated that patients with del(11q22.3) and del(17p13.1) have a shorter duration of response to this regimen. A recent update of this study with a median follow-up of 117 months showed that the median OS was 85 months with 71% of patients alive at 5 years. The median PFS was 42 months with 27% progression free at 5 years. Importantly, an estimated 13% of patients remained free of progression at almost 10 years of follow-up. IgV_H-mutated disease status was favorably associated with extended PFS and OS, but not having high-risk cytogenetics was associated with a favorable OS. Notably, there were no cases of treatment-related myeloid neoplasms occurring before relapse contrasting with prior studies with fludarabine- and alkylator-containing regimens.

Fludarabine, Cyclophosphamide, and Rituximab

The most active phase II results with chemoimmunotherapy have been achieved by the MD Anderson group with a combination FCR regimen in both previously treated and untreated CLL. A total of 177 evaluable patients with previously treated CLL received fludarabine 25 mg/m^2 and cyclophosphamide 250 mg/m^2 on days 2 to 4 of cycle 1 and on days 1 to 3 of cycles 2 to 6 in addition to rituximab 375 mg/m^2 on day 1 of cycle 1 and 500 mg/m^2 on day 1 of cycles 2 to 6. An ORR of 73% with a 25% CR rate and 16% nodular PR rate was reported, and 12 of 37 patients (32%) in CR achieved molecular remission. The same authors administered FCR to 300 previously untreated CLL patients; the ORR was 95%, with 72% of patients attaining a CR. Six-year PFS was 51%, and OS was 77%. Features associated with poor response included high β_2M, del(17p13.1), age older than 70 years, and elevated white blood cell count above 150 $\times$ 10^9/L. Late infections or other complications were uncommon except for treatment-related myeloid neoplasias (tr-MN), which occurred in 3% of patients. The outcome of patients with tr-MN was poor irrespective of treatment. In a multivariate analysis of patients receiving fludarabine-based therapy at MD Anderson, FCR therapy was significantly associated with improved survival, thereby validating the experience with FR, suggesting that rituximab therapy was improving OS.

The benefit of adding rituximab to FC was confirmed by the GCLLSG, which randomized 817 physically fit, previously untreated CLL patients, ages 30 to 81 years, to fludarabine 25 mg/m^2 on days 1 to 3 and cyclophosphamide 250 mg/m^2 IV on days 1 to 3, with or without rituximab 375 mg/m^2 day 0 of cycle 1 and 500 mg/m^2 day 1 of cycles 2 to 6 every 28 days for 6 cycles. A total of 761 patients were evaluable for response. FCR induced higher OR (95 vs. 88%) and CR rates (44 vs. 22%) than FC. Median PFS was 32.8 months for FC and 51.8 months for FCR, and the largest benefit for FCR was observed in Binet stage A and B patients. The OS rate at 37.7 months favored FCR over FC (84% vs. 79%; $P = .01$). FCR resulted in more grade 3 and 4 neutropenia (34% vs. 21%) and leukopenia (24% vs. 12%), but there was no difference in severe infections or treatment-related deaths between the two arms. As with other chemoimmunotherapy trials in CLL, neutropenia was more common with FCR than FC. Emerging from this study were numerous biologic correlative studies showing the most predictive test of long term PFS and OS was attainment of minimal residual disease (MRD)–negative disease by high-sensitivity flow cytometry. In addition, patients with unmutated IgV_H disease had a shorter PFS and OS with both FCR and FC, although rituximab appeared to benefit both treatment groups. All genetic groups benefited from rituximab with the exception of the del(17p13.1) and normal karyotype patients, who had similar outcomes to FC or FCR treatment. Further long-term follow up of this study is ongoing for late complications and assessment of newer prognostic factors identified since initiation of this study. Thus the benefit of chemoimmunotherapy in the frontline treatment of CLL has been clearly demonstrated by studies of both FR and FCR.

Bendamustine and Rituximab

Based on promising single agent activity of bendamustine in previously treated CLL and in vitro studies demonstrating synergy between bendamustine and rituximab, the GCLLSG examined the feasibility and safety of this combination in a phase II study in 78 relapsed CLL patients. Bendamustine was administered at a dose of 70 mg/m^2 days 1 and 2 and rituximab at 375 mg/m^2 on day 0 of cycle 1 and 500 mg/m^2 on day 1 of cycles 2 to 6. Using an intent-to-treat analysis, the ORR was 59% with a CR of 9%. The median PFS was 14.7 months. Response was poor (7%) in the del(17p) patients. Severe infections occurred in 13% of patients. Grade 3 or 4 neutropenia, thrombocytopenia, and anemia were documented in 23%, 28%, and 17% of patients, respectively.

A follow-up study (CLL2M) included a total of 117 symptomatic, previously untreated CLL patients who were treated with

bendamustine (90 mg/m^2 on days 1 and 2) and rituximab (375 mg/m^2 in cycle 1 and 500 mg/m^2 in cycle 2 to 6). Treatment was administered every 28 days for up to 6 cycles. Demographics of the patients included a median age of 64 years with 48% having Binet C disease. The ORR was 91%, and the CR was 33%. After 18 months, 76% of patients were still in remission, and median PFS had not been reached at the time of the report. The treatment was well tolerated with cytopenias and infections being most problematic. Treatment-related mortality (TRM) was 2.6%. Patients with all genomic groups except for del(17p13.1) responded favorably. Based on these encouraging phase II data, the GCLLSG initiated a phase III study comparing BR with FCR (CLL10) in previously untreated, physically fit CLL patients that is ongoing at this time.

Chlorambucil and Rituximab

Based on the success of chemoimmunotherapy and the potential absence of benefit of nucleoside analogs in elderly CLL patients, Hillmen and colleagues initiated a study in 100 elderly, previously untreated CLL patients combining rituximab (day 1; 375 mg/m^2 IV cycle 1, 500 mg/m^2 cycles 2-6) and chlorambucil (days 1-7; 10 mg/m^2/day PO) every 28 days for 6 cycles. Patients were permitted to receive 6 additional cycles of chlorambucil if they had evidence of continuing clinical response at 6 cycles. The median age was 70 years. OR rate on an intent-to-treat analysis was 82%, with nine patients achieving CR, 58 patients showing partial response (PR), 15 patients showing nodular PR (nPR), and 11 patients with stable disease (SD). Median PFS to date is 23.5 months. The response in this study was significantly higher in patients receiving chlorambucil alone in the CLL4 study, suggesting a benefit to rituximab. A second Italian phase II study using a similar combination regimen of chlorambucil and rituximab together demonstrated similar favorable response data. Based on these phase II data, a randomized phase III study comparing chlorambucil versus chlorambucil with either rituximab or obinutuzumab is currently ongoing by the GCLLSG, and a similar study is studying ofatumumab and chlorambucil versus single-agent chlorambucil in previously untreated elderly or unfit CLL patients (see box on What Is the Role of Rituximab in Chronic Lymphocytic Leukemia?).

What Is the Role of Rituximab in Chronic Lymphocytic Leukemia?

Studies of rituximab to this point have demonstrated modest single-agent clinical activity in both previously untreated CLL patients using the weekly dosing schedule and in the relapsed state using more intensive dosing regimens. Rituximab does not have activity against CLL with del(17p13.1). For this reason, rituximab monotherapy is generally used in either of these settings only if more definitive therapy cannot be administered because of other comorbid conditions. Rituximab's greatest contribution is to combination therapy both in symptomatic, previously untreated CLL patients and relapsed patients receiving the FR or FCR regimen, particularly in younger patients. Phase III studies have demonstrated the clear benefit of chemoimmunotherapy over traditional chemotherapy alone and, combined with multiple retrospective analyses, established chemoimmunotherapy as the standard of care in CLL. Several phase II studies have combined rituximab with other therapies such as bendamustine, chlorambucil, and pentostatin–cyclophosphamide that might be more tolerable to the more common older patients. Phase III studies with several of these agents are ongoing at this time. Inclusion of rituximab in alternative chemoimmunotherapy regimens for patients not appropriate for fludarabine-containing regimens is reasonable and our current practice approach. Although several phase II studies of maintenance rituximab have been published after completion of chemoimmunotherapy, the benefit of this is uncertain. Until ongoing phase III results are available justifying maintenance rituximab in CLL, it should not be used outside of the context of a clinical trial.

Alemtuzumab

Alemtuzumab is a humanized monoclonal antibody against CD52, a cell-surface glycopeptide expressed on virtually all human lymphocytes, monocytes, and macrophages, a small subset of granulocytes, but not erythrocytes, platelets, or hematopoietic stem cells. CD52 is expressed on all CLL cells and indolent B-NHL cells. The physiological function remains unknown, but crosslinking of CD52 on B-cell and T-cell lymphoma cell lines inhibits their cell proliferation. Alemtuzumab has been demonstrated to mediate apoptosis, CDC, and ADCC of CLL cells in vitro. CD52 is not shed, internalized, or modulated and is therefore an ideal antigen for targeted immunotherapy. However, the ubiquitous expression of CD52 on normal lymphocytes and monocytes is predictive of the increased neutropenia, lymphopenia, and infectious complications observed with alemtuzumab therapy.

Phase I studies of alemtuzumab have established a dose of 30 mg IV three times per week for 4 to 12 weeks. Alemtuzumab induced significantly more infusion-related toxicity than rituximab, but stepped-up dosing diminished initial infusion-related toxicity and made administration of the antibody tolerable and feasible. Three milligrams is given on the first day, 10 mg on day 2, and 30 mg on day 3; after dose escalation, patients receive 30 mg thrice weekly. Several clinical studies have established a role for alemtuzumab in CLL. In a multicenter European phase II study, alemtuzumab was administered at 30 mg thrice weekly for up to 12 weeks to 29 recurrent and refractory CLL patients. The ORR was 42%, but only one patient (4%) achieved a CR. Alemtuzumab cleared CLL cells from the peripheral blood in 97% of patients but was less effective at eliminating BM (36%) or nodal disease (7%).

The pivotal CAM211 trial administered the same regimen of alemtuzumab therapy to 93 heavily pretreated, fludarabine-refractory CLL patients. The ORR was 33%, but only 2% of patients achieved a CR. Median time to progression for responders was 9.5 months, with a median OS of 16 months for all patients and 32 months for responders. The median peripheral blood CLL count decreased by more than 99.9%, but the antibody was less effective against nodal disease, particularly in patients with bulky lymph nodes larger than 5 cm in diameter. Although 90% of patients with lymph nodes measuring less than or equal to 2 cm responded, with 64% achieving resolution of adenopathy, only 12% of patients with lymph nodes greater than 5 cm responded with no patients attaining resolution of their adenopathy. All patients were placed on prophylactic antibiotics and antiviral agents, and treatment-related toxicity was manageable. Patients with a poor performance status did markedly worse than patients with no or minimal symptoms from their disease, likely owing to their reduced ability to tolerate the hematologic and infectious side effects of alemtuzumab, and no patients with ECOG performance status greater than 1 responded to therapy. The activity of alemtuzumab was later confirmed by a multi-institutional, compassionate use study in 136 patients with fludarabine-refractory CLL.

The GCLLSG explored the use of subcutaneous (SC) alemtuzumab for patients with relapsed CLL in an attempt to diminish infusion-related toxicity associated with this regimen. This study administered alemtuzumab 3, 10, and 30 mg IV during week 1 followed by 30 mg SC thrice weekly for 4 to 12 weeks. A total of 109 heavily treated patients were treated. The ORR (34%), CR rate (4%), median duration of PFS (7.7 months), and median OS (19.1 months) were virtually identical to the results achieved with IV alemtuzumab in the CAM211 study. Additionally, the response rate was similar in patients with high-risk cytogenetic abnormalities with del(11q22.3) and del(17p13.1). Infusional toxicity with this treatment was minimal, and inflammation at the sites of injection was mild. Toxicity included grade 3/4 neutropenia (56%), thrombocytopenia (57%), and anemia. Grade 3/4 infections (29%) and cytomegalovirus (CMV)

infections (8%) were also observed. In this study, long-term survival was best predicted by subsequent allogeneic SCT indicating the poor prognosis of this refractory patient group.

Based on promising data in relapsed disease, a phase II clinical trial of alemtuzumab administered at a dose of 30 mg SC three times per week for up to 18 weeks to 41 previously untreated patients with CLL was performed. Except for transient grade 1 to 2 fever, adverse reactions after the first were minimal. The ORR was 81% on an intent-to-treat basis, and 87% of the 38 patients who received at least 2 weeks of treatment responded. Alemtuzumab was more active in this setting with an ORR of 87% and CR of 29%. Some patients who achieved a CR in the BM required the full 18 weeks of therapy to do so, suggesting that prolonged administration was necessary to clear CLL cells from the BM. On the basis of these promising results in the upfront setting, the CAM307 study prospectively randomized 297 previously untreated CLL patients to oral chlorambucil 40 mg/m^2 every 4 weeks for 12 cycles or alemtuzumab 30 mg IV three times per week for up to 12 weeks. All patients on the alemtuzumab arm received prophylaxis for *Pneumocystis carinii* and varicella zoster. Alemtuzumab achieved a superior ORR (83% vs. 55%), CR rate (22% vs. 2%), and duration of PFS (23.3 vs. 14.7 months). Response in del(11q22.3) and del(17p13.1) patients was improved over chlorambucil, but the median PFS was less than 1 year, indicating a very modest benefit of this treatment. Non–infusion-related toxicity between the two treatment arms was similar except for more nausea with the chlorambucil and increased CMV viremia (52.4% vs. 7.5%) with alemtuzumab. This registration study had no late analysis for survival outcome or late toxicity associated with this treatment.

Owing to the ubiquitous expression of CD52 on lymphocytes and monocytes, immunosuppression and infectious complications constitute the most concerning toxicity of alemtuzumab. Although alemtuzumab also depletes B cells, CD8$^+$ T cells, NK cells, and monocytes, the antibody's most profound effect is its ablation of CD4$^+$ T lymphocytes. This delayed recovery of CD4$^+$ T-lymphocytes has been observed by multiple investigators. The absolute CD4$^+$ T-cell count reached a nadir of 2/μL by week 4 and increased only to 84/μL by week 12 in the CAM211 trial. Furthermore, alemtuzumab depleted CD52$^+$ myeloid peripheral blood dendritic cells, inhibiting the ability of peripheral blood mononuclear cells (PBMCs) to present antigen to purified CD4$^+$ T lymphocytes.

Given this prolonged immunosuppression, alemtuzumab should be administered carefully, particularly when the antibody is given in combination with other immunosuppressive agents such as fludarabine. Patients receiving alemtuzumab are at an increased risk for bacterial, fungal, viral, and other opportunistic infections as demonstrated by multiple clinical trials. For instance, 55% of patients in the CAM211 study developed infections (27% grade 3-4), and 13% experienced septicemia. Patients receiving alemtuzumab must therefore be placed on appropriate prophylaxis for *P. carinii* pneumonia and varicella zoster infection/reactivation. Additionally, CMV infection monitoring by PCR or hybrid capture assays should be performed regularly during and for at least 2 to 3 months after therapy with alemtuzumab. Alternatively, the MD Anderson group has demonstrated in a small randomized trial that valganciclovir prophylaxis during alemtuzumab treatment eliminates the risk of CMV reactivation. If prophylactic therapy is not used, patients who reactivate CMV should be treated appropriately. With these prophylactic measures, alemtuzumab can be administered safely and with acceptable infection-related morbidity in most patients. The approach of CMV monitoring and treatment of increasing CMV viremia is the approach that our group takes when administering alemtuzumab, caused by the cytopenias associated with valganciclovir and cost of this therapy that is prohibitive to most patients. Other toxicities with alemtuzumab, including infusion events (more common with IV administration) and cytopenias, are treated with traditional support provided to patients with leukemia. Although alemtuzumab received full marketing approval for initial and relapse therapy of CLL, this agent is very uncommonly used in CLL as monotherapy at this time because of the serious toxicity and modest benefit it offers to these patients.

Chemoimmunotherapy With Alemtuzumab

Several groups have pursued adding alemtuzumab, similar to rituximab, either concurrently or sequentially with several chemotherapeutic agents for the treatment of previously treated or symptomatic untreated CLL patients. Results of these studies have not yet translated to a standard therapy used for the treatment of patients with CLL. In virtually all of the studies, increased toxicity has been observed compared with standard regimens. Additionally, in two studies adding alemtuzumab to FCR, the MD Anderson group was unable to demonstrate added benefit in high-risk CLL patients. Because these approaches will likely not be applied in future treatment regimens for CLL, they are not summarized further.

Alemtuzumab as Consolidation Therapy After Chemotherapy

Given the ability of alemtuzumab to clear BM of CLL cells and to eliminate MRD, several investigators have examined the use of alemtuzumab as consolidation therapy after initial induction therapy with fludarabine. In one report, alemtuzumab was administered at a dose of 10 or 30 mg IV thrice weekly for 4 weeks to 58 patients who had responded to their most recent therapy but still had residual disease. The ORR was 53%, and the response rate was dose dependent; 65% of patients who received 30 mg responded compared with 39% of patients who received 10 mg. Eleven of 29 patients (38%) achieved MRD-negative BM, and the TTP was not reached after a median follow-up of 24 months. In addition, the TTP was significantly longer in patients who had no BM MRD after alemtuzumab consolidation. Similar findings were reported by the GCLLSG, which randomized 21 eligible patients, who had responded to fludarabine or Flu/Cy induction therapy but still had persistent disease, to observation (n = 10) or alemtuzumab 30 mg IV thrice weekly for up to 12 weeks (n = 11). The study was discontinued early as a result of increased toxicity in the alemtuzumab arm; six of 11 patients experienced grade 4 hematologic toxicity, and seven of 11 patients developed grade 3 or 4 infectious complications, including four patients with CMV. However, five of six evaluable patients had no MRD in the BM with alemtuzumab consolidation. After a median follow-up of 48 months, the median PFS favored the alemtuzumab arm (not reached vs. 20.6 months) with only three of 11 patients who received alemtuzumab relapsing. On the basis of these promising results, the GCLLSG FLL2i study is currently evaluating the optimal dose and schedule of alemtuzumab consolidation after initial fludarabine-based therapy.

The administration of alemtuzumab SC has also been examined in the consolidation setting in two additional trials. The CALGB 19901 study administered fludarabine 25 mg/m^2 IV daily for 5 days every 28 days for 6 cycles followed by alemtuzumab 30 mg either IV or SC thrice weekly for 6 weeks with previously untreated CLL. Of the 85 evaluable patients enrolled, four (5%) attained a CR, and 43 (51%) attained a partial response after fludarabine induction for an ORR of 55%. Thirty-nine patients received IV alemtuzumab for consolidation with improvement in CR to 27% and ORR to 73%. Twenty patients received SC alemtuzumab consolidation with improvement in CR to 17% and ORR to 69%. Toxicity from IV alemtuzumab included infusion-related reactions and infection. Mild local inflammation was common from SC alemtuzumab. Nine of 59 (15%) patients had CMV infections with one death. Given the lack of intensity of induction therapy with fludarabine, CALGB planned a second study with more intensive induction as part of CALGB 10101. Patients received fludarabine and rituximab (FR) similar to that administered in CALGB 9712 for 6 cycles. Three months after completion of FR, patients with stable disease or better response received SC alemtuzumab using stepped-up dosing week 1 followed by 30 mg three times per week for 5 weeks. The ORR was 90% and CR rate was 29%. Of 102 patients enrolled, 58 received alemtuzumab; 28 (61%) of 46 patients achieving PR after FR attained CR after alemtuzumab. By intent to treat for all patients at completion

of therapy, the ORR was 90% and CR rate was 57%. With median follow-up of 36 months, the median PFS was 36 months, 2-year PFS was 72%, and 2-year OS was 86%. In patients achieving CR after FR, alemtuzumab was associated with five deaths resulting from infection (viral and *Listeria* meningitis and *Legionella,* CMV, and *Pneumocystis* pneumonias), which occurred up to 7 months after the last therapy. Most importantly, alemtuzumab in this study did not abrogate the adverse outcome associated with high-risk genetic features, including del(17p13.1), del(11q22.3), and IgV_H-unmutated CLL. Additionally, PFS and OS in this study did not appear better than the FR regimen previously reported by CALGB. Future efforts with this approach are not being pursued by the US Intergroup.

What Is Alemtuzumab's Role in Chronic Lymphocytic Leukemia?

As a result of the ubiquitous expression of CD52 on lymphocytes and monocytes, alemtuzumab causes significantly more hematologic and immune toxicity than does rituximab, and careful monitoring of and prophylaxis for potential infections is required for any administration of alemtuzumab. Although the different toxicities of alemtuzumab are manageable, its integration into CLL therapy has been somewhat challenging based on the difficulty of administering it with other myelosuppressive or immunosuppressive therapies used for CLL either concurrently or as consolidation therapy. Additionally, although it is effective in all high-risk groups based on genetic abnormalities, including those with del(17p13.1), it does not work well for patients with bulky lymph nodes. These numerous limitations have greatly impaired the use of alemtuzumab in the treatment of CLL. Furthermore, the advent of newer therapeutic agents with activity against del(17p13.1) may offer clinicians safer yet effective treatments for this high-risk population. Although several such agents have shown activity against genetically high-risk CLL, none of these agents has yet shown the ability to achieve CR in the BM and eradicate MRD to the same degree as alemtuzumab.

TREATMENT OF PATIENTS WITH RELAPSED CHRONIC LYMPHOCYTIC LEUKEMIA

The approach to reinitiating therapy for CLL patients who have relapsed after initial therapy is similar to that applied for initial therapy assessment. Patients need not receive therapy at the first sign of relapse. Rather, patients should have an indication for treatment, as discussed earlier. Patients should have repeat interphase FISH analysis of the peripheral blood or BM aspirate because patients may acquire additional cytogenetic abnormalities, most notably del(17p13.1), as their CLL becomes more advanced. The incidence of del(17p13.1) increases from 5% of patients at initial diagnosis to nearly half of heavily treated patients with advanced CLL, and acquisition of this abnormality has profound implications on treatment, as will be discussed later. IgV_H mutational analysis does not need to be performed if such information has been obtained previously because a patient's IgV_H mutational status does not change with time. A BM should be performed if cytopenias are present to confirm that CLL is the cause and to exclude other potential causes of cytopenias such as transformed lymphoma, prolonged BM toxicity from prior therapy, or development of treatment-related myelodysplasia. Patients should be treated according to the indications outlined in Table 76-4. An algorithm to our treatment approach to first relapsed CLL is summarized in Fig. 76-2. In general, for patients younger than the age of 70 years who have experienced a good remission with initial therapy for longer than 24 months, an FCR or BR regimen, preferably in combination with an investigational agent, is suggested. If a complete remission is obtained in the absence of del(17p13.1), our approach at this point is to observe. If a del(17p13.1) is present or a complete response to therapy is not obtained, we generally will consider a nonmyeloablative allogenetic SCT. For patients relapsing who are 70 years or older, retreatment with the same therapy, BR or an alternative antibody or investigational agent can be considered. In general, we do not administer FCR to this patient population owing to concerns of increasing toxicity.

Ofatumumab in Relapsed Chronic Lymphocytic Leukemia

Ofatumumab

Ofatumumab is a fully human type I anti-CD20 monoclonal antibody that was initially approved for the treatment of CLL in late 2009. In vitro, it has improved CDC, ADC, and direct killing (with cross-linking), compared with rituximab. Ofatumumab has a different binding epitope of CD20 than rituximab, binding to both the small and large extracellular loops of CD20, and a slower off rate as well. Ofatumumab is able to kill rituximab-resistant CLL cells because of greater induction of CDC and its ability to kill cells with low CD20 expression, which may be relevant given the low CD20 expression on CLL cells. Based on these promising data, a phase I/II study of ofatumumab, given at doses of 500 to 2000 weekly for four doses in 33 relapsed or refractory CLL patients, demonstrated that it is generally well tolerated even at higher doses. Ofatumumab was active, with an ORR of 50% in the highest cohort treated at 2000 mg. Infusion-related adverse events were similar to those reported with rituximab and decreased after the first infusion. Infections were fairly common, occurring in 51% of patients, including one fatal infection. These results prompted a pivotal, single-arm study of ofatumumab administered as 8 weekly infusions of ofatumumab followed by 4 monthly infusions. Patients received 300 mg as the first dose to minimize infusion-related reactions, and the dose was increased to 2000 mg for all subsequent infusions. Patients included in this study were required to be fludarabine refractory and to also be alemtuzumab-refractory (FA-refractory group; $n = 95$) or to have bulky lymphadenopathy larger than 5 cm (BF-refractory group; $n = 111$). The ORR, as assessed by an independent review committee, was 51% for the FA-refractory group and 44% for the BR-refractory group, with two CRs observed in the BF-refractory group. All other responses were partial. The median duration of response was 5.7 months in the FA-refractory group and 6.0 months in the BF-refractory group with most patients progressing during treatment. The median PFS was 5.5 months in both the FA-refractory and BF-refractory groups. Median OS was 14.2 months and 17.4 months, respectively. For rituximab-treated ($n = 117$), rituximab-refractory ($n = 98$), and rituximab-naive ($n = 89$) patients, the OR rates were 43%, 44%, and 53%, respectively; median PFS was 5.3, 5.5, and 5.6 months, respectively; and median OS was 15.5, 15.5, and 20.2 months, respectively. Thus prior exposure to rituximab did not affect the response to ofatumumab.

The presence of del(17p13.1) was associated with a lower response rate and shorter median PFS in both patient groups (37% vs. 56% and 3.3 months vs. 5.5 months in FA-refractory group; 22% vs. 49% and 3.8 vs. 5.6 months in BF-refractory group). Thus, in contrast to rituximab, ofatumumab is active as a single agent in del(17p13.1) CLL but has inferior activity compared with alemtuzumab. Toxicity included infusion-related reactions, infections, and cytopenias. This trial led to accelerated approval of ofatumumab for the treatment of patients with fludarabine- and alemtuzumab-refractory CLL, and a phase III study of ofatumumab versus physician's choice of therapy in bulky, fludarabine-refractory CLL is ongoing. Determination of the clinical superiority of ofatumumab over rituximab will require randomized trials comparing equivalent doses. Currently, several phase III studies of ofatumumab in combination with chlorambucil (initial treatment), FC (salvage), or as single agent maintenance therapy in CLL are ongoing.

Stem Cell Transplantation

For many years, autologous and allogeneic SCTs were generally used for treatment of CLL late in the course of the disease. However, trials

of SCTs have indicated that patients with multiply relapsed and chemotherapy-resistant disease are at highest risk for both relapse and TRM. Additionally, many patients with heavily treated CLL cannot be adequately cytoreduced or disease control cannot be maintained for a sufficient period of time to obtain insurance approval and find a suitable allogeneic donor, producing a selection bias that often excludes patients with the most refractory or aggressive disease from actually receiving SCT. The recognition that patients with poor prognostic features such as del(11q22.3) and del(17p13.1) and patients who fail to achieve CR after receiving regimens such as FCR have a short remission duration to initial therapy has prompted many transplant centers to consider earlier application of allogenic SCT as therapy for CLL, including its use as consolidation treatment after induction therapy for the highest risk patients. Referral of high-risk CLL patients at the time of initial treatment to an experienced transplant center for evaluation, potential tissue typing of the patient and his or her siblings, and initiation of an unrelated donor search (if needed) should be considered. Although autologous SCT has been used historically as a treatment for CLL and has been reviewed elsewhere, nonmyeloablative allogeneic SCT is the preferred modality for most patients requiring a transplant unless a suitable allogeneic donor is not available. Autologous SCT is no longer utilized in CLL because of a lack of a survival advantage, only modest benefit in PFS, and a high risk of tr-MN with this modality. Therefore, autologous SCT is not reviewed in this chapter.

Myeloablative Allogeneic Stem Cell Transplantation

Allogeneic SCT offers several theoretical advantages over autologous SCT in CLL. The use of an allogeneic donor provides an immunologic graft-versus-leukemia (GVL) effect for patients with CLL. Limited data suggest that TBI-containing conditioning regimens are superior to chemotherapy-only regimens in CLL transplant patients. A small study of 25 patients demonstrated a 100-day TRM of 57% in patients who received busulfan and cyclophosphamide (Bu/Cy; $n = 7$), compared to 17% for patients who received a TBI regimen ($n = 18$). Five-year actuarial survival was 56% for 14 patients transplanted with TBI regimens during 1992-1999. A study of Cy/TBI in 28 CLL patients observed a 100-day TRM of 11%. Five-year PFS and OS were 78% and 78% for chemosensitive patients compared with 26% and 31% for refractory patients.

A retrospective EBMT study of 135 patients showed 54% 3-year OS and 40% 100-day TRM. The IBMTR reported similar findings, with 45% 3-year OS and 30% 100-day TRM in 242 patients. The high TRM may be explained in part by the late stage of the disease in many of these patients. Median time from diagnosis to SCT was 41 and 46 months in these two studies, and 37% of patients in the EBMT study were chemorefractory before transplant. In a Canadian study of allogeneic SCT in 30 CLL patients, the 5-year EFS and OS were both 39%, with 48% OS for patients with sibling donors. The role of unrelated donor allogeneic SCT was examined by a multicenter study in 38 patients, 92% of whom received TBI. Five-year FFS and OS were 30% and 33%, and TRM was 38%. Although there are no prospective randomized studies, a retrospective comparison showed a 3-year DFS of 57% for allogeneic SCT versus 24% for purged autologous SCT. Finally, allogeneic SCT appears to overcome the adverse prognosis associated with an unmutated IgV_H; an analysis of 34 CLL patients who underwent SCT found that only two of 14 patients who received allogeneic SCT relapsed, compared with 13 of 20 patients who underwent autologous SCT.

Thus myeloablative allogeneic SCT may provide superior DFS to patients with CLL compared with autologous SCT. Although the 3-year DFS after allogeneic SCT is approximately 50%, longer follow-up is needed to determine if the disease remissions are durable. However, this DFS advantage is offset by significantly higher TRM, thus limiting the use of allogeneic SCT in CLL. Limited data indicate that Bu/Cy may be particularly toxic in this population; by contrast, TBI regimens have acceptable TRM. To preserve the immunologic GVL effect while reducing TRM, the focus of clinical SCT research in CLL has turned to nonmyeloablative, or reduced-intensity, allogeneic SCT.

Nonmyeloablative Allogeneic Stem Cell Therapy

Ideally, the goal is to harness the GVL effect of allogeneic SCT for patients with CLL while reducing TRM from acute graft-versus-host-disease (GVHD), acute infection, and organ toxicity associated with myeloablative conditioning. Fludarabine, busulfan, and ATG were administered to 30 German CLL patients; the stem cell source was a matched related ($n = 15$) or unrelated ($n = 15$) donor. Grade 2 to 4 acute GVHD was observed in 56% of patients, and 75% developed chronic GVHD. Responses were seen in 93% of patients, with 40% achieving CR. Of note, it took up to 2 years for patients to achieve CR, suggesting a GVL effect. All patients achieved a molecular CR by PCR, but only six patients were in continued molecular CR after a median follow-up of 2 years. Two-year TRM, PFS, and OS were 15%, 67%, and 72%, respectively.

The EBMT retrospectively examined 77 CLL patients who received a variety of nonmyeloablative conditioning regimens, followed by allogeneic SCT. The 1-year TRM was 18%, and the 2-year probability of relapse was 31%. Two-year DFS and OS were 56% and 72%, respectively. Nineteen patients received donor lymphocyte infusions (DLIs) for relapse or incomplete donor chimerism, but only seven responded to DLI (37%). Unfortunately, this study was complicated by the heterogeneity of conditioning regimens and the use of ATG or Campath-1H for T-cell depletion of the grafts in 40% of patients. A retrospective analysis of 73 CLL patients who underwent nonmyeloablative SCT and 82 patients who underwent myeloablative allogeneic SCT showed that the TRM was significantly reduced in the former group, with a hazard ratio of 0.4; however, there was no difference in EFS or OS between the two groups.

Sixty-four patients received 200 cGy of TBI, with ($n = 53$) or without ($n = 11$) fludarabine followed by an allogeneic SCT from a related ($n = 44$) or unrelated ($n = 20$) donor. The 2-year DFS and OS were 52% and 60%, respectively, and the 2-year TRM was 22%. The incidence of relapse at 2 years was 26%, and the mortality due to relapse was 18%. Finally, a British study of 41 CLL patients who received fludarabine, melphalan, and alemtuzumab followed by an allogeneic SCT from a related ($n = 24$) or unrelated ($n = 17$) donor observed a 2-year OS and TRM of 51% and 26%. Eleven patients (27%) relapsed and received escalated donor lymphocyte infusions, but only three patients had a sustained response to DLI. Five patients (12%) have died of relapse.

Nonmyeloablative allogeneic SCT may be superior to autologous SCT in obtaining clinical and molecular remissions in high-risk CLL patients with unmutated IgV_H because of a GVL effect. Seven of nine patients (78%) in a German study became negative by PCR for allele-specific IgVH after d100 post-SCT; attainment of molecular CR occurred after DLI or development of chronic GVHD. In contrast, only six of 26 control CLL patients (23%) achieved a PCR-negative state after autologous SCT. Similar findings were reported by a Spanish study of nonmyeloablative SCT in 30 CLL patients. The 6-year EFS and OS were 92% and 90% for patients with unmutated IgV_H or del(11q). Several other studies from MD Anderson, Germany, and the University of Washington transplant groups have confirmed these findings. Thus an immunologic GVL effect appears to be important in CLL and may confer a long-term survival advantage for allogeneic SCT, given sufficient time.

Investigational Agents Currently in Phase II–III Testing for Relapsed CLL

Although numerous therapeutic agents are currently being tested in CLL, many of these agents will ultimately fail to gain an indication

for CLL or are many years away from approval. Attention is therefore directed toward agents that are currently in phase III registration studies based on preliminary efficacy in relapsed CLL.

Lenalidomide

Lenalidomide, or 3-(4-amino-1,3-dihydro-1-oxo-2*H*-isoindol-2-yl)-2,6-piperidinedione (Revlimid), is an immunomodulatory drug (IMiD) that is a more potent analog of thalidomide. Lenalidomide is approved for marketing in multiple myeloma and transfusion-dependent myelodysplasia. Lenalidomide has clinical activity in a variety of other malignancies, including CLL. Two initial studies examining either an intermittent 25 mg PO daily for 21 days and 5 mg with dose escalation to 10 mg PO as tolerated given as continuous therapy were pursued initially in relapsed CLL. The higher dose, intermittent schedule was active with an ORR of 47% and 9% CR. Major side effects of this therapy were cytopenias, rash, and tumor flare, which in some cases can be life threatening. The continuous, low-dose regimen had a 32% intent-to-treat ORR with a 7% CR rate. Toxicity was less with this schedule but still included cytopenias in most. On the basis of these promising phase II clinical studies, a large, multicenter trial randomizing patients to low-dose (10 mg) or high-dose (25 mg) lenalidomide was undertaken, which was halted early because of life-threatening adverse events in patients receiving the higher dose of therapy. Subsequent studies have shown that lower doses of lenalidomide administered as continuous treatment in patients with relapsed CLL are feasible. These have prompted several single agent studies in symptomatic, previously untreated CLL in which the clinical activity has ranged from an ORR of 56% to 65% with up to 10% CR. Most provocative from these studies was the observation that lenalidomide reversed the hypogammaglobulinemia observed in CLL patients. PFS with this treatment is approximately 2 years. Toxicity, including tumor flare, cytopenias, rash, and infection, has been noted but is manageable.

In an attempt to understand both the pathogenesis of tumor flare and immunoglobulin recovery, laboratory work by our group and others has demonstrated that lenalidomide activates CLL cells to promote expression of CD154, CD80, and CD86 that makes them more immunogenic, visible to the immune system, and potentially proliferative in node and BM sanctuaries. These activated CLL cells also can serve as a second signal with T cells to promote normal B cells to produce antibody, thus possibly explaining why hypogammaglobulinemia is reversed in many of these patients. Other studies have shown lenalidomide enhances T-cell and NK cell response to CLL cells.

Moving forward, efforts with lenalidomide have focused in part on combining it with other agents, most notably anti-CD20 antibodies such as rituximab and ofatumumab, or as consolidation therapy after purine analog or bendamustine-based induction therapy. Preliminary reports have suggested diminished tumor flare when administered with therapeutic antibodies but increased cytopenias and adverse events when combined with chemoimmunotherapy regimens. Similarly, lenalidomide has been given as consolidation maintenance as part of several phase II chemoimmunotherapy trials. In one such study with PCR-based treatment, consolidation therapy with lenalidomide appeared to potentially extend PFS over that previously seen with PCR alone. Based on the clinical activity observed with lenalidomide, two phase III registration studies are currently underway examining lenalidomide versus chlorambucil for elderly CLL and as a consolidation therapy after second treatment for this disease. The recent recognition of the profound immunologic effects of lenalidomide on CLL suggest that it might also serve as an effective agent earlier in the course of the disease or as an adjuvant to vaccine-based approaches. These are currently being pursued at this time as well by several different groups. Because of the relative modest activity in heavily pretreated patients, other alternatives in first-line therapy, and potential for life-threatening tumor flair and other toxicity with lenalidomide, this agent should only be considered as part of a well-designed clinical trial despite its FDA approval for other indications (MDS and multiple myeloma).

Agents Targeting B-Cell Receptor Signaling Pathways

B-cell receptor signaling and microenvironmental signals are now known to be important in both proliferation and protection of CLL cells in BM and nodal sites. These findings have prompted the introduction of several novel, orally available kinase inhibitors. In particular, agents targeting the δ isoform of PI3-kinase and Bruton tyrosine kinase (Btk) have shown very promising clinical activity and, more importantly, durability of remission over time in refractory CLL patients. The results of these studies are summarized below.

Fostamatinib disodium is a multitargeted kinase inhibitor whose primary target is syk. An early phase I/II study of fostamatinib in NHL and CLL was undertaken based on preclinical data showing a potential for therapeutic benefit. This phase II study noted modest activity in NHL patients, but six of 11 (55%) CLL/SLL patients responded with rapid reduction of nodal disease and transient lymphocytosis suggestive of CLL cell compartmental mobilization. Because of off-target effects of this drug, tolerability was not optimal with many patients noting diarrhea, fatigue, cytopenias, hypertension, and nausea. Although this agent did not move forward for development in CLL, it served as the first hint that targeting syk and other BCR signaling pathways may be worthwhile.

GS1101 (formerly CAL-101) is an orally bioavailable, isoform specific, PI3-kinase-δ inhibitor that, at therapeutic levels obtained in patients, does not inhibit other isoforms of PI3-kinase. Genetic mouse models knocking out PI3-kinase delta demonstrate predominantly a B-cell defect, absent B1 lymphocytes, and disrupted BCR signaling. Preclinical studies by our group and later confirmed by others demonstrated that GS1101 promotes the apoptosis of CLL cells via a PI3-kinase-δ pathway and inhibits signals from the microenvironment that protects CLL cells from apoptosis. Based in part on these data, a phase I study in healthy volunteers showed this agent to be well tolerated, and subsequently a large phase I study in NHL, CLL, multiple myeloma, and AML was undertaken. GS1101 was active at all dose levels tested, with the dose-limiting toxicity being reversible transaminitis that generally occurs during the first 2 months of therapy in approximately 5% to 20% of patients, depending on histology. Although patients with NHL experienced a higher incidence of transaminitis, perhaps caused by occult liver involvement by tumor, the incidence of transaminitis was less than 5% in CLL patients. In the phase I study, 57 relapsed CLL patients have been treated with a median of 5 prior regimens. Notable with this treatment was that 90% had a 50% or greater nodal response but with 26% also having class specific lymphocytosis. However, 14 of 54 CLL patients (26%) achieved durable remissions that exceeded 1 year. Responses were noted across all genetic groups of CLL. Toxicity with this treatment included pneumonia and liver function abnormalities but not myelosuppression. Subsequent studies have been undertaken with GS1101 combining it with rituximab, ofatumumab, and bendamustine/rituximab, showing that combination therapy with GS1101 is feasible and does not result in increased liver toxicity. Given the high rate of response and durable remissions observed with GS-1101, registration studies with this agent in CLL are now being undertaken.

PCI32765 is a potent, irreversible inhibitor of Btk. Btk is a tyrosine kinase in the Tec family of tyrosine kinases and is an essential element of the BCR signaling pathway. Genetic knock-out or inactivation of Btk in mice produces predominantly a B-cell defect with absent B1 lymphocytes, diminished B cells, and disrupted BCR signaling. Mutations in Btk in humans result in a more profound humoral immune defect with absent B-cells, immunoglobulin, and infections. Preclinical work with PCI32765 demonstrated disruption of BCR signaling and in vivo activity in spontaneous

canine lymphoma models with documented targeted inhibition of Btk. Preclinical trials demonstrated that PCI32765 promotes apoptosis of CLL cells, inhibits activation of PI3-kinase, ERK1, and NFκB by external microenvironment signals, and also prevents CLL proliferation. Collectively, these preclinical studies prompted phase I/II studies with PCI32765 in NHL and CLL. The phase I study of PCI32765 was completed after two dose levels above where Btk inhibition occurred without obtaining a maximum tolerated dose. At the highest dose, toxicity was quite mild, including grade 1/2 nausea, diarrhea, infections, rash, and fatigue. Activity was seen at all doses, including in nine of 16 CLL/SLL patients. A phase IB/II study in CLL patients was undertaken in which 61 patients with relapsed disease were treated daily at a dose of 420 mg ($n = 27$) or 840 mg ($n = 34$). The patients' median age was 60 years, and the median number of prior therapies was four. Median follow-up for the 420 mg and 840 mg cohorts was 12.6 months and 9.3 months, respectively. As with GS1101, the clinical response was characterized by early lymphocytosis accompanied by rapid reduction in the size of lymph nodes, later followed by reduction of lymphocytosis in the majority of patients. Response by IWCLL 2008 criteria was similar (67% and 68%) by dose, with 22% and 24% additional patients having 50% nodal reduction but incomplete resolution of lymphocytosis (nodal response). PFS was estimated to be 86% at 1 year. Of note, only three of 61 patients have gone off study because of progressive disease. Additionally, response has been noted independent of associated genetic abnormalities del(17p13.1). Subsequent studies have been undertaken with PCI3276 combining it with ofatumumab and bendamustine–rituximab, showing that these combinations are feasible. Based on these promising results, registration studies in CLL are now being undertaken with PCI32765.

At the time of writing this chapter, it is apparent that these new inhibitors of BCR signaling will have great impact on the treatment of CLL, particularly given the well-tolerated and durable remissions that are being achieved in relapsed patients. At select CLL centers that also focus on allogeneic SCT, a decline in the number of transplants is being observed based in part on the durable remissions induced in patients considering transplant who have elected to delay this option.

Chimeric Antigen Receptor T-Cell Therapy

To date, efforts at reverting T-cell immune suppression toward the tumor cells have been relatively limited. A major development has been preclinical and early phase I studies demonstrating that ex vivo transfected T-cells with chimeric T-cell receptors bearing both CD3 and also a B cell–specific antigen (most often CD19) have great potential to eradicate established B-cell tumors after administration into both xenograft models and, recently, patients with refractory CLL. Significant development and optimization with chimeric antigen receptor T-cell therapy (CAR-T) cells remains, however, before this can be readily administered widely.

Other Agents in Late Clinical Trials for Chronic Lymphocytic Leukemia

Several other promising therapeutics are in late phase II/III clinical trials for CLL. Those with documented activity in this disease that have potential to be approved for use in CLL are describe d here.

The cyclin-dependent kinase inhibitor flavopiridol is a first-generation molecule with approximately a 50% response rate in highly refractory CLL with the dose-limiting side effect of tumor lysis syndrome but producing durable remissions in a subset of CLL patients, including those with del(17p13.1). Off-target effects of flavopiridol promoting diarrhea and fatigue prompted transition to a second-generation CDK inhibitor dinaciclib, which has a more favorable therapeutic index. This agent has completed phase I studies in CLL with similar efficacy of flavopiridol, including dose-limiting toxicity of hyperacute tumor lysis syndrome but absent many of the off-target effects of flavopiridol. Dinaciclib will be entering a phase III licensing study for therapy of relapsed CLL.

The bcl-2 antiapoptotic protein is overexpressed in CLL and has been shown to disrupt apoptosis in this disease. Although the bcl-2 antisense molecule genasense did not meet the bar for regulatory approval in CLL, attempts to target bcl-2 with small molecule inhibitors have proceeded. The most potent inhibitor of bcl-2, Navitoclax (formerly ABT263), has demonstrated single agent activity in relapsed CLL with a target specific (BCL-XL) dose-limiting toxicity of profound thrombocytopenia. A second-generation inhibitor (ABT199) that lacks off-target effect on BCL-XL is now entering phase I studies.

GA101 is a type II human CD20 directed antibody that is also glycoengineered to have enhanced NK-cell mediated ADCC. As a type II CD20 antibody, GA-101 has the ability to induce direct apoptosis of CLL and NHL tumor cells but lacks CDC activity. GA101 has completed phase I studies in NHL and CLL where clinical activity was shown in a dose-dependent fashion. GA101 is now being tested in a phase III registration study in combination with chlorambucil versus chlorambucil alone. In addition, it is being tested as both a single agent in previously untreated CLL and also in combination with FC.

Therapeutic antibodies or small modular immune pharmaceuticals (SMIP) targeting surface antigens, including CD19 (Xm5574), CD37 (TRU-016, IMGN529 and MAb 37.1), and BAFF-R (VAY736), are under development. Additionally, therapeutic agents targeting signal transduction pathways (HSP-90 inhibitors, AKT inhibitors, ILK inhibitors, NFκB inhibitors, and PP2A activating agents) are in early clinical development. Finally, agents targeting epigenetic events or innate immune activation (CpG oligonucleotides or IL-21) have promising data to support their ongoing early clinical investigation.

Management of Chronic Lymphocytic Leukemia in Specialized Centers

Given the recent advent of prognostic markers and treatment options in CLL, a recent study that examined the impact of physician expertise on patient outcomes in CLL has shown that disease-specific expertise made significant differences in outcomes across all aspects of patient care from prognostic evaluation to choice of therapy. These findings suggest that the expertise of the physician caring for the patient with CLL/SLL is an independent prognostic variable that may not be related to the number of patients he or she manages. We therefore recommend that all patients with newly diagnosed CLL/SLL should be managed in consultation with a CLL expert at a tertiary care center with access to the most recent molecular diagnostic tools.

SPECIAL CLINICAL SCENARIOS IN CHRONIC LYMPHOCYTIC LEUKEMIA

Young Patients (Younger Than 50 Years of Age) With Chronic Lymphocytic Leukemia

As mentioned previously, CLL is a disease of elderly adults, with only 10% of patients being younger than the age of 50 years at diagnosis. Although CLL patients live for a prolonged period of time, young patients without comorbid illnesses have a great potential to have their lives significantly shortened by the disease, irrespective of their cytogenetic abnormalities. Additionally, stress associated with job performance, insurance coverage maintenance, and disease-related symptoms are most significant in this age group. Special attention to psychosocial issues related to CLL should occur early in the course of the disease to allow patients to maintain or resume their normal lifestyles as soon as possible. In the absence of impending need for therapy, our approach is generally not to empirically pursue HLA typing or examine transplant options before the development of

symptomatic disease. When therapy is initiated for this group of patients, consideration of aggressive intervention to promote prolonged remission duration is always a top priority. SCT is generally considered for patients in this age group with CLL with high-risk cytogenetic abnormalities in first remission and for all patients who relapse after initial therapy unless high-risk cytogenetic abnormalities are not present and a complete response is attained.

Patients With Fludarabine-Refractory Chronic Lymphocytic Leukemia

Fludarabine-refractory CLL is generally considered to exist if a patient has not responded to a fludarabine-based therapy or relapses within 6 months of completing such a regimen. Several retrospective studies have documented a short survival time (9-12 months) and a particularly high frequency of both bacterial and opportunistic infections in this patient population. With the introduction of chemoimmunotherapy as initial therapy, another poor prognostic group includes patients relapsing within 2 years of FCR- or FR-based therapy. These patients have a significantly shorter PFS with subsequent therapies. New therapeutic agents such as bendamustine, ofatumumab, and alemtuzumab have been evaluated in this setting and have modest activity and produce relatively short remissions. New investigational agents (CAL-101, PCI-32765, CDK inhibitors, bcl-2 antagonists) have been evaluated in this patient population and demonstrated clinical activity. Consideration of allogeneic SCT in this setting is essential. The complexities of complications, poor therapeutic options, and acute features of this advanced CLL can put great strain on the patient, family members, and general hematologist alike. Referral of such patients to tertiary CLL centers for access to clinical trials and treatment of these specialized needs should be considered for patients with fludarabine-refractory or short remission chemoimmunotherapy CLL.

Richter Syndrome

Richter syndrome (RS), the development of high-grade lymphoma in patients with CLL, was described by Maurice Richter in 1928. Over the years, the classification of RS has expanded to include lymphoid malignancies such as Hodgkin disease, lymphoblastic lymphoma, PLL, and hairy cell leukemia (see Fig. 76-4, *A* to *C*). Incidence estimates range from 2.8% to 10.7%. Recent studies have suggested that the development of RS may be related to the evolution of an abnormal clone unrelated to the underlying CLL clone. Clearly identifiable risk factors for the development of RS are lacking, and its development has been shown to be independent of disease stage, duration of disease, type of therapy, or response to therapy. However, the presence of diffuse lymphomatous involvement, advanced Rai stage, IgV_H-unmutated disease, ZAP-70 expression, high LDH, del(17p13.1), high serum β_2M levels, and recently NOTCH1 mutations may predict the development of RS. RS is characterized by sudden onset of B symptoms (fever, night sweats, weight loss) and rapidly progressive lymphadenopathy at any anatomic site. Rarely, the lymphomatous clone may arise from the bone or an extranodal site. Laboratory abnormalities including anemia, neutropenia, and thrombocytopenia may be due to large-cell transformation in the BM. A rapid increase in the serum LDH is seen in the majority of patients. The diagnosis is generally made after examining the histology of a rapidly enlarging lymph node, which typically reveals large-cell lymphoma. PET scans can be helpful in these patients to localize the most hypermetabolic node for biopsy. Historically, RS has been treated with regimens similar to those used for the treatment of large-cell lymphomas involving multiple agents such as methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, bleomycin, dexamethasone, cytarabine, and cisplatin (e.g., MACOP-B, CHOP-B, DHAP, and VAD). Recently, regimens incorporating oxaliplatin (OFAR) have been reported, although their benefit in RS is uncertain over traditional lymphoma regimens. Our institution prefers dose-adjusted infusional therapy (R-EPOCH) for the initial treatment of these patients. The duration of response and the OS rates are dismal, with most patients likely to die within 6 months of their diagnosis despite aggressive therapy. Long-term remissions and survival have been reported in a few patients after allogeneic SCT, but this approach is associated with a high TRM. When Richter transformation occurs, consolidation with allogeneic SCT is the preferred treatment.

Similar to RS, prolymphocytic transformation (PT) occurs in fewer than 10% of patients with CLL. PT is characterized by the appearance of large, immature prolymphocytes in the peripheral blood, which make up 10% to 50% of the peripheral circulating malignant lymphoid cells. These patients may be older with advanced disease and have more pronounced lymphadenopathy and splenomegaly. PT is associated with a poor outcome, with limited survival beyond 1 year. These patients often have del(17p13.1) but do appear to respond to many of the newer therapies coming forward for treatment of CLL. Allogeneic SCT may also be used as a potentially curative therapeutic option.

Secondary Malignancies in Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia is associated with an increased risk of secondary malignancies. These include not only hematologic malignancies such as MDS and AML associated with the use of chemotherapeutic agents but also solid tumors such as Kaposi sarcoma, malignant melanoma, and laryngeal and lung cancers. The increased incidence of secondary malignancies may be attributable to multiple reasons, including the immune dysfunction associated with CLL, the frequent infectious complications, the carcinogenic side effects of the various chemotherapeutic agents, and the increased and close medical surveillance that patients with CLL receive from trained oncologists.

Hypersensitivity in Chronic Lymphocytic Leukemia to Mosquitoes and Insect Bites and Treatment

Patients with chronic lymphocytic leukemia commonly exhibit an exaggerated cutaneous response to insect bites. This was first reported in 1965 by Robert Weed, who documented a hypersensitivity reaction to insect bites in eight of 97 patients with CLL over a 13-year period. The reaction is characterized histologically by the presence of a dermal infiltrate composed of a mixed population of T and B cells, eosinophils, and eosinophilic granule protein. The extent of eosinophilic degranulation may also correlate with the severity of symptoms. Clinically, these patients present with recurrent, painful, bullous eruptions that may be traced to an insect bite in some instances. In limited cases, we have also observed that CLL patients have hypersensitivity to bed bugs, and this should be considered in the differential diagnosis. Identification and avoidance of known triggers may be useful in some cases, but most patients are unable to identify the inciting exposure. Treatment with a short course of steroids is usually effective, but these patients frequently relapse and may require multiple courses of therapy. Dapsone and chlorambucil may also be useful in severe, recurrent cases.

Other cutaneous conditions are also common in CLL patients, with up to 45% reporting some form of skin involvement. These include petechial, purpural, or ecchymotic lesions related to thrombocytopenia; infectious eruptions such as herpes simplex and zoster; and direct leukemic involvement in fewer than 10% of all patients with advanced disease.

INFECTIONS IN PATIENTS WITH CHRONIC LYMPHOCYTIC LEUKEMIA

Infectious complications remain the leading cause of morbidity and mortality in patients with CLL. The incidence of infectious

complications has been estimated to be as high as 80% with a mortality rate of approximately 60%. Various factors contribute to the increased incidence of infectious complications in CLL, the most important being progressive disease affecting host immunity through an impaired antibody response and hypogammaglobulinemia; weakened host cellular immune responses, including impaired macrophage function; a decrease in T-regulatory cells; and, finally, the acquired defects after immunosuppressive chemotherapy.

Recent studies have examined predictors of severe infections in patients with CLL. In their retrospective analysis of infection-related mortality in 280 patients, advanced age, clinical stage B or C disease, unmutated IgV_H, and positive CD38 status have been identified as independent predictors of both shorter time to first infection and infection-related mortality. Other risk factors that may also have an impact on development of infections include type of initial therapy and development of renal insufficiency.

Historically, sinopulmonary infections from encapsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae* have been the most common cause of infectious complications in patients with CLL. With the recent use of more potent cytotoxic chemotherapy and the resultant profound myelosuppression, an increased frequency of severe pulmonary infections, bacteremia, and gram-negative infections has been reported. Infections caused by atypical organisms such as *Listeria monocytogenes, Nocardia* spp., *Mycobacterium* spp., and *Neisseria meningitidis* are relatively infrequent in patients who receive conventional chemotherapy. Treatment for presumed infection should be initiated empirically in CLL patients who develop fever because fever in CLL patients usually indicates an active infection. Therapy should be tailored to the particular organ involved and the sensitivity of the organism. Prophylactic antibiotics can be initiated for debilitated patients with high-risk disease and significant immune dysfunction.

Viral infections are also commonly encountered in CLL patients (see Fig. 76-3, *D* and *E*). Herpesvirus infections are especially common in patients treated with nucleoside analogs and alemtuzumab. Chronic, indolent oropharyngeal and circumoral herpes simplex virus (HSV) outbreaks are more frequent than aggressive, disseminated visceral disease. Reactivation of Epstein-Barr virus (EBV) has been implicated in some cases of Richter transformation. Other viruses may cause severe systemic disease in patients with CLL. Varicella zoster virus (VZV) can cause herpes zoster, herpetic neuralgia, and rarely meningoencephalitis, parvovirus B19 can cause severe polyarthritis and pure RBC aplasia, and JC polyoma virus has been implicated in the development of progressive multifocal leukoencephalopathy. Management of these infections depends on early recognition of disseminated viral disease, timely initiation of antiviral therapy in cases of HSV and EBV, and a low threshold for the introduction of prophylactic acyclovir and supportive therapy. All patients should be provided instruction to identify the signs and symptoms of herpes virus infection at the time of diagnosis of CLL.

Fungal infections are not typically observed in CLL in the absence of treatment with corticosteroids or other immunosuppressive therapy for autoimmune complications arising from CLL. Cryptococcal meningitis, pneumonia, and fungemia are well-recognized events in patients with CLL and are associated with significant morbidity and mortality. More cases of *P. carinii* pneumonia, systemic candidiasis, and aspergillosis have been reported since the advent of combination nucleoside analog therapy with steroids. Treatment of the infection is dictated by the identification of the particular organism. Trimethoprim–sulfamethoxazole is routinely used as effective prophylaxis against *P. carinii* infections, especially during and immediately after the use of nucleoside analogs or alemtuzumab. Fungal prophylaxis with posaconazole may also be used during protracted therapy with high-dose steroids to avoid invasive aspergillosis.

Prophylactic Strategies for Infections

Routine use of prophylactic antibiotics is generally not used for CLL despite the higher frequency of infections observed in patients with this disease. Early recognition of signs and symptoms of infection and prompt initiation of empiric broad-spectrum antibiotics is probably a more feasible and cost-effective approach. When chemoimmunotherapy is used that includes a nucleoside analog or alemtuzumab therapy, prophylaxis for herpes simplex and varicella zoster should be used, particularly in older patients. Trimethoprim–sulfamethoxazole (or other alternative *P. carinii* pneumonia prophylaxis) should also be administered in this setting.

Hypogammaglobulinemia is virtually always present in advanced CLL, and several studies have examined whether intravenous immunoglobulin (IVIG) replacement therapy can reduce the incidence and severity of infectious complications. Patients receiving IVIG in a double-blind, placebo-controlled trial experienced significantly fewer bacterial infections than the placebo group. The therapy was well tolerated with few adverse reactions, but there was no observed benefit in terms of preventing viral or fungal infections. However, other studies have shown an almost 50% reduction in the number of serious infections per year with IVIG infusions. Limited data support the use of IVIG at a higher dose of 600 mg/kg every 4 weeks to reduce the number and severity of respiratory infections. However, the prohibitive cost of IVIG therapy and the fact that it has not been shown to prolong survival argues against its empiric use in all patients. IVIG should be used judiciously and reserved for patients with advanced disease and recurrent infections. The usual dose used is 200 to 400 mg/kg every 4 to 6 weeks as needed, with the aim of keeping the trough serum IgG concentration greater than 500 mg/dL. This is something our group routinely does for refractory patients or those who have more than two infections requiring hospitalization during 1 year.

Among the strategies for preventing infections in this patient population is immunization. CLL patients, however, typically respond poorly to pneumococcal and influenza vaccines. Advanced age, advanced disease stage, hypogammaglobulinemia, and low levels of soluble CD23 influence the rate of responses to immunizations. Soluble CD23, a degradation product of membrane-bound CD23, is involved in several aspects of B-cell activation and proliferation and has a synergistic effect on histamine release. Histamine has a direct inhibitory effect on immunoglobulin production by B cells in vitro via histamine type-2 (H2) receptors and acts as an immune regulatory factor that can be modulated by H2 receptor antagonists. Thus responses to vaccines may be further enhanced by adjuvant treatment with H2 blockers. Studies have shown that response to protein-conjugated vaccines may be enhanced by ranitidine in CLL patients to as much as 90% compared with 43% in the control group. Unfortunately, this response is not seen with polysaccharide vaccines. Recent studies have indicated that protein-conjugated vaccines may be more immunogenic, as shown by a more significant immune response to *Haemophilus influenzae* type b conjugate vaccine than to plain polysaccharide antigen. In light of the paucity of data on an appropriate immunization schedule, we suggest a modified immunization plan based on the recommendations of the Advisory Committee on Immunization Practices. This includes use of Prevnar 13 for pneumococcal prophylaxis and avoiding live vaccines, including the varicella zoster virus.

Growth factors such as G-CSF or granulocyte macrophage colony-stimulating factor (GM-CSF) can be used prophylactically in high-risk, severely neutropenic patients to shorten the duration and severity of neutropenia.

AUTOIMMUNE COMPLICATIONS OF CHRONIC LYMPHOCYTIC LEUKEMIA

Patients with CLL have a greater predisposition to develop autoimmune hematologic complications, including AIHA, idiopathic thrombocytopenia purpura (ITP), and pure RBC aplasia. AIHA occurs in up to 37% of CLL patients at some time during the course of their disease. A small proportion (10%-15%) of patients may present with AIHA at diagnosis. AIHA can have a varied presentation, with patients developing signs of anemia, including weakness, lethargy, dyspnea on exertion, and dizziness over a period of months.

Examination may reveal pallor, jaundice, hepatosplenomegaly and lymphadenopathy. Hemolysis can cause mild to moderate indirect hyperbilirubinemia, elevated LDH levels, and hemoglobinuria. The direct antiglobulin Coombs test result is positive in up to 74% of patients with CLL, but not all patients develop hemolysis. Most of the antibodies produced are warm reactive, but patients can occasionally present with cold agglutination syndrome. The antibodies are mostly polyclonal and usually a product of normal B cells rather than the leukemic clone.

In contrast to the high frequency of AIHA in CLL, ITP or ITP and AIHA, or Evans syndrome, occurs less frequently in CLL. These events can occur throughout the entire course of CLL and are much more difficult to diagnose because of the absence of multiple implicating laboratory features as seen with autoimmune hemolytic anemia.

Given the small number of patients with AIHA, there are no data from controlled trials to guide the management of AIHA. Glucocorticoids have been used since the 1940s and are considered the first line of therapy. Most patients will respond to prednisone at a dose of 1 mg/kg for 10 to 14 days followed by a slow taper over 2 to 3 months, depending on the extent of hemolysis. ORRs of up to 90%, with 65% CRs, have been reported with the use of steroids. Unfortunately, approximately 60% of patients relapse when steroid therapy is stopped. Rituximab 375 mg/m^2 weekly for four weeks is often effective for steroid-resistant AIHA or ITP and if steroid withdrawal is not possible. Because of the long-term morbidity of prolonged steroid administration in CLL and data demonstrating benefit to concurrent steroids and rituximab for rapid withdrawal of corticosteroids in ITP, our group recently has begun giving these two concurrently at diagnosis of ITP or AIHA unless contraindicated (e.g., hepatitis B). IVIG, the next line of treatment, induces responses in 40% of patients for both AIHA and ITP. Thrombopoietin agonists are effective for refractory ITP in CLL and could also be considered at this time. Cyclosporine A (CSA) has been used for refractory AIHA and ITP of CLL at 5 mg/kg/day given in divided doses twice daily. The dose should be adjusted to maintain a serum level of around 100 to 150 μg/dL. Other treatment modalities include splenectomy or splenic irradiation, alkylating agents, or therapy (FCR or FR directed at the disease if active). Treatment of the underlying CLL is generally required for long-term control of autoimmune cytopenias. However, our practice is to first control the autoimmune process with steroids or other therapies before considering treatment of the underlying CLL. Supportive therapy with periodic RBC transfusions is also important in the management of AIHA.

There are limited data on the routine use of erythropoiesis-stimulating agents (ESAs) in patients with Coombs-negative anemia. These agents are most effective in patients with low levels of endogenous erythropoietin and may improve the quality of life and reduce the frequency of transfusions in this subset of patients. However, given the recent data on the increased risk of thromboembolic events and higher sudden death rates in patients treated with these agents, judicious use is recommended. ESAs are never recommended when rapid correction of hemoglobin is required.

Pure RBC aplasia (PRCA) is a relatively rare T cell–dependent complication associated with CLL, but an incidence as high as 6% has been reported. PRCA was first described by Dameshek and colleagues in 1967. It is characterized by a hypoproliferative anemia that can be detected even in early-stage CLL and is thought to be caused by cytotoxic effects of suppressor T cells on erythroid progenitor cells. Higher numbers of these CD3, CD8, and CD57 coexpressing cells have been shown to gradually accumulate in the BM of patients with PRCA. Abeloff and Waterbury described the first remission of PRCA to cyclophosphamide therapy in 1974, and Chikkappa and colleagues described the first case of response to CSA. Subsequent larger studies have shown a response rate as high as 63% with 300 mg/day of oral CSA. Mild reversible nephrotoxicity may warrant dose adjustment in some patients. Most patients exhibit a response by having reticulocytosis within the first 10 to 14 days, but maximal response may occur an average of 10 weeks after the start of therapy. However, steroid therapy at a dose of 1 mg/kg/day of prednisone remains the first line of treatment. If a response is not obtained in 4 weeks, CSA should be added to the regimen. Other agents that have shown promising activity in treating PRCA include rituximab, IVIG, alemtuzumab, and antithymocyte globulin. Packed RBC transfusions are usually indicated in patients who are clinically symptomatic from severe anemia.

A number of other complications, most of which are autoimmune in nature, have been reported in patients with CLL. These complications include paraneoplastic pemphigus, angioedema caused by acquired C1-inhibitor deficiency, and nephrotic syndrome. As a result of autoimmune involvement of various organs, patients with CLL may have abnormal serum chemistry profiles and liver function tests.

FUTURE DIRECTIONS

Advances in the molecular biology of CLL over the past 2 decades have translated into new diagnostic tests that allow better assessment of initial prognosis and also to assign treatment. Additionally, multiple new therapies have come forward, and progress is being made to extend remission duration and improve the quality of life of CLL patients. Additionally, medications and interventions to support complications that arise from CLL have also been introduced. Overall, the future for patients with CLL remains brighter based on these past efforts and likely will improve further with continued laboratory and clinical research ongoing in this disease. In particular, the BCR kinase inhibitors have potential to transform treatment and outcome of patients with CLL.

CHAPTER 77

HAIRY CELL LEUKEMIA

Farhad Ravandi

The most recent revision of the World Health Organization (WHO) classification of hematopoietic neoplasms is intended to provide a disease specific classification for the diagnosis and potential treatment of these disorders and has continued to further incorporate modern cytogenetics and molecular data to better define disease subsets that may be amenable to different treatment strategies. Hairy cell leukemia (HCL) is one of the diseases exemplifying the importance of the application of appropriate diagnostic techniques and treatment strategies in order to obtain the best results in the individual patient.[1] The disease was first described by Bouroncle and colleagues in 1958. The term *hairy cell leukemia* was first used to describe the disorder by Schreck and Donnelly in 1966 and is derived from the observation of hair-like projections from mononuclear cells giving rise to a frayed cell surface appearance.

The evolution of therapeutic strategies in patients with HCL over the past 25 years has led to a significant change in the natural history of the disease. Using the currently available drugs, the majority of patients with this disease achieve complete remission (CR), and the published survival curves from several large series are similar to those for appropriate age-matched individuals without the disease. At the same time, recent research efforts have led to a better understanding of the molecular mechanisms responsible for the disease pathogenesis. Several studies, using modern techniques, have demonstrated the persistence of minimal residual disease (MRD) after therapy with nucleoside analogs in the majority of patients without consensus on the significance of such MRD. The role of monoclonal antibodies, naked or conjugated with toxins, in the management of HCL, as well as their ability to eradicate MRD, is under investigation. The possibility of such strategies of chemoimmunotherapy leading to further improvements in the outcome of patients with HCL needs to be further investigated.

EPIDEMIOLOGY

HCL is an uncommon lymphoid malignancy, accounting for only 2% of lymphoid leukemias, with approximately 600 to 800 new patients diagnosed each year in the United States.[1] The disease is more common in whites and occurs more frequently in men than women by a ratio of 4 to 1.[1] The median age at diagnosis is reported by most studies to be in the 50s. However, it is possible that the disease is underreported in the older population. The Swedish Cancer Registry has maintained records on the incidence of the disease for several decades and has shown a stable incidence since the 1980s. It reports the median age at diagnosis of 62 years, suggesting less rigid diagnostic efforts in older patients.

HCL has been diagnosed in patients in their 20s and 30s but is exceptionally rare in children. Using data from the 17 population-based cancer registry areas in the United States, the National Cancer Institute's Surveillance Epidemiology and End Results (SEER) program reported that the incidence of the disease was stable in the decades between 1978 and 2004 with a rapid rise in age-specific incidence ratios until approximately 40 years and then at a slower pace beyond that age.

ETIOLOGY AND CELL OF ORIGIN

Several reports have suggested an association between development of HCL and exposure to several compounds, including benzene, organophosphorus insecticides, and other solvents. However, such association has not been confirmed by other reports. Exposure to radiation, wood dust, or agricultural chemicals, and a previous history of infectious mononucleosis have also been suggested as predisposing factors, but a direct, causal association has not been established with any of these or other factors.

Morphologically and phenotypically, the cells in HCL have no resemblance to any of the normal stages of B-cell development and maturation; past studies have debated their cell of origin. Initially, because of morphologic and functional similarities between hairy cells and cells of the monocyte/macrophage system, HCL tumor cells were thought to be derived from a cell transformed from the reticuloendothelium. Korsmeyer demonstrated the rearrangement of the B-cell receptor (BCR) immunoglobulin genes in HCL, demonstrating for the first time the B-cell origin of the disease. Recently, several studies have increased our understanding of the cell of origin in HCL allowing for a better description of pathogenic mechanisms responsible for its development.[2]

In lymphoid cells, the analysis of the immunoglobulin variable region genes provides a tool for the delineation of the clonal history of cells at which lymphoid neoplasms originate, identifying whether antigen encountered by a normal mature B cell has resulted in somatic mutation (Fig. 77-1). This process occurs within the germinal centers (GC) of lymph tissues and may be associated with isotype switching. The enzyme activation–induced cytidine deaminase (AICD) is critical for both processes. Tumor cells from various B-cell malignancies are arrested at a number of stages along normal B-cell differentiation, conserving the immunogenetic characteristics of the stage-specific cell. The analysis of immunoglobulin variable gene regions can provide information about whether the cell of origin has undergone somatic mutation and isotype switching. Several reports have clearly demonstrated that in more than 85% of patients with HCL the tumor cells express switched immunoglobulin isotypes, and their rearranged variable region genes have undergone somatic mutations.[3] Furthermore, HCL cells express AICD, the enzyme that is critical for both processes.[3] This suggests that the cell of origin in the majority of HCL cases has transited through the GCs of peripheral lymphoid tissue having undergone the GC reaction.[2] Of interest, in about 40% of cases of HCL, the leukemia cells express multiple immunoglobulin heavy chain isotypes, with dominance of IgG3 but only a single light chain, suggesting that clonally related multiple isotypes coexist in single hairy cells. Therefore this subset of the disease may be arrested at a point after isotype switching and before exit from the GC. However, other lines of evidence suggest a post-GC origin.[2]

Another study by Arons and colleagues provided evidence that in the majority of patients with classic HCL (83% of 102 cases), the cell of origin is post-GC with mutated immunoglobulin heavy chain variable region.[4] This contrasted with historic data for patients with CLL, in which case about half of cell origins are unmutated. They also reported higher usage of certain immunoglobulin gene families and a difference in mutational frequency among these genes.[4] Furthermore, by demonstrating that the mutations fulfilled

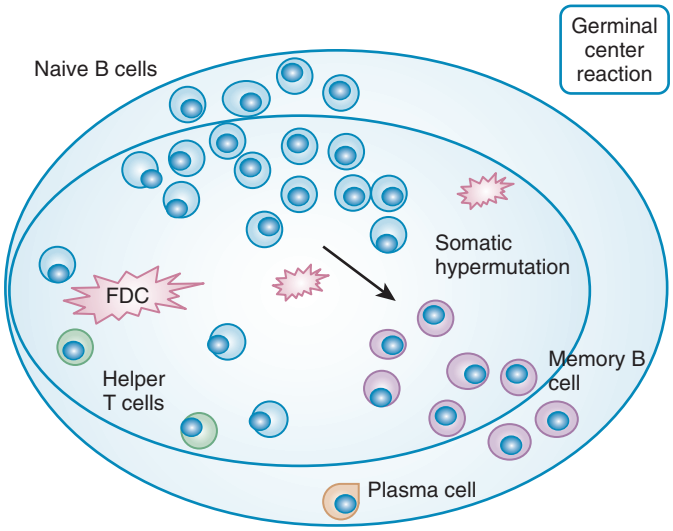

Figure 77-1 GERMINAL CENTER REACTION. The process of somatic hypermutation and isotypic switch in the germinal center.

predefined characteristics of a canonical and nonrandom event, Arons and colleagues provided further evidence suggestive of an antigen-driven process.

The post-GC origin of HCL is supported by gene expression profiling studies comparing HCL cells with cells from other lymphoid neoplasms, as well as with naive and memory B cells.[5] Samples from various HCL patients displayed a homogeneous pattern of gene expression that was clearly distinct from other B-cell lymphomas and was related to post-GC memory B cells.[5] Other investigators have reported this remarkably stable genome in HCL. Furthermore, when compared with memory B cells, HCL cells had a remarkable conservation of proliferation, apoptosis, and DNA metabolism programs but differed significantly in the expression of genes controlling cell adhesion and response to chemokines.[5] Against the hypothesis of a memory B-cell origin is the lack of expression by hairy cells of the memory B-cell marker, CD27. However, CD27-negative memory B cells have been described in humans, and hairy cells may lose this marker as a result of the neoplastic transformation.

As lymph node involvement in HCL is uncommon, the post-GC cell of origin is likely to originate from the spleen or the bone marrow, sites involved by the disease almost invariably. A number of reports have suggested that HCL may originate from the B cells of the splenic marginal zone (SMZ). Normal SMZ B cells are mainly memory B cells. Vanhentenrijk and colleagues, using comparative expressed sequence hybridization (CESH) studies, demonstrated that hairy cells had an expression profile consistent with a splenic expression signature that most likely reflected the expression profile of spleen-specific components, such as the sinusoidal lining cells from the red pulp and the marginal zone B cells from the white pulp.

Recently, Tiacci and colleagues reported the presence of *BRAF* V600E mutations in each of 47 patients with HCL and no mutations in the cells from patients with 195 peripheral B-cell lymphomas or leukemias, which were also evaluated.[6] Using whole-genome sequencing they identified, in an index patient, five missense somatic clonal mutations, including a heterozygous mutation in *BRAF* that resulted in a BRAF V600E variant protein.[6] Since *BRAF* V600F is known to be oncogenic in other tumors, Tiacci and colleagues focused on this mutation and analyzed the subsequent 46 cases as well as the patients with other lymphomas. They also demonstrated expression of phosphorylated MEK and ERK, showing constitutive activation of the RAF-MEK-ERK mitogen-activated protein kinase (MAPK) pathway in HCL.[6] This discovery has potential significance in the understanding of the pathogenic mechanisms of HCL; its applications in diagnosis and treatment of this disease are likely to increase with further research.

CLINICAL PRESENTATION AND DIAGNOSIS

Typically, the majority of patients present with pancytopenia and splenomegaly with the associated fatigue, left upper quadrant abdominal pain, fever and infections, and/or bleeding problems (Table 77-1). Common presenting features include significant anemia, seen in up to 85% of patients, thrombocytopenia in about 60% to 80%, and leukopenia in 60% of patients; these cytopenias can be severe and life-threatening and are likely multifactorial, with hypersplenism and marrow infiltration being the more important contributors. Monocytopenia is a characteristic finding. Circulating hairy cells are typically scant in most patients and frequently absent. Hairy cells are small- and medium-sized lymphoid cells with an oval or indented (bean-shaped) nucleus with homogeneous chromatin that is less clumped than normal B cells (Fig. 77-2).[1] Nucleoli are typically absent or inconspicuous and the cytoplasm abundant and pale blue in color with circumferential "hairy" projections. Electron micrographs of hairy cells clearly demonstrate their distinctive and complex surface features with multiple surface folds and clusters of short microvilli, creating an appearance unique to hairy cells (Fig. 77-3).

Bone marrow involvement can be interstitial or patchy with the infiltrate characterized by widely spaced nuclei due to the abundant cytoplasm, giving rise to the commonly described "fried egg" appearance (Fig. 77-4).[1] Occasionally, an increase in the bone marrow reticulin fibrosis, as well as significant loss of the hematopoietic elements, leads to a "dry tap." Bone marrow fibrosis is caused by the production and assembly of a fibronectin matrix by hairy cells and the deposition of fine reticulin fibers (mainly composed of type III collagen fibrils) by fibroblasts.[2] Hairy cells express isoenzyme 5 of acid phosphatase, which imparts resistance to treatment with tartaric acid, with virtually all cases being positive for tartrate-resistant acid phosphatase (TRAP)

(Fig. 77-5). Combined expression of DBA44 and TRAP by immunohistochemical analysis is highly specific and useful for arriving at the diagnosis. More recently, immunostaining for annexin A1 (ANAX1) has been reported to be very specific for HCL.[7] ANAX1 can be used to distinguish HCL from its variant form and from other lymphoid neoplasms such as splenic marginal zone lymphoma (SMZL).[1,7] Cyclin D1 (encoded by *CCND1* gene) is frequently expressed, but this is not secondary to translocation involving *CCNDI,* unlike mantle cell lymphoma. In a proportion of patients, the bone marrow is hypocellular with the loss of hematopoietic elements, which can result in an erroneous diagnosis of aplastic anemia. Immunostaining for antigens such as CD20 may be helpful to detect the abnormal B-cell infiltrate, hence prompting more specific stains for HCL.[1]

HCL cells have a characteristic immunophenotype with flow cytometry being an important element of diagnostic evaluation in this disease (Table 77-1). Hairy cells strongly express CD45 and gate within the monocytic region when analyzed by CD45 versus side scatter, which is typically devoid of monocytes. They exhibit a mature B-cell phenotype and commonly express one or more heavy chains and monotypic light chains (κ and λ light chains in equal numbers of patients). They express B-cell associated antigens CD19, CD20, CD22, FMC7, and CD79b but typically lack CD5, CD10 (positive in about 10%), and CD23 (positive in about 20%) expression. No single marker is specific for distinguishing HCL from other B-cell neoplasms; however, the antigens CD11c, CD103, CD123, as well as the interleukin (IL)-2 receptor α-subunit (CD25), are typically expressed in HCL. Bright expression of CD22 and CD20 is also seen, which can be important therapeutically. Among the patients evaluated in one study, CD52 was also universally expressed.

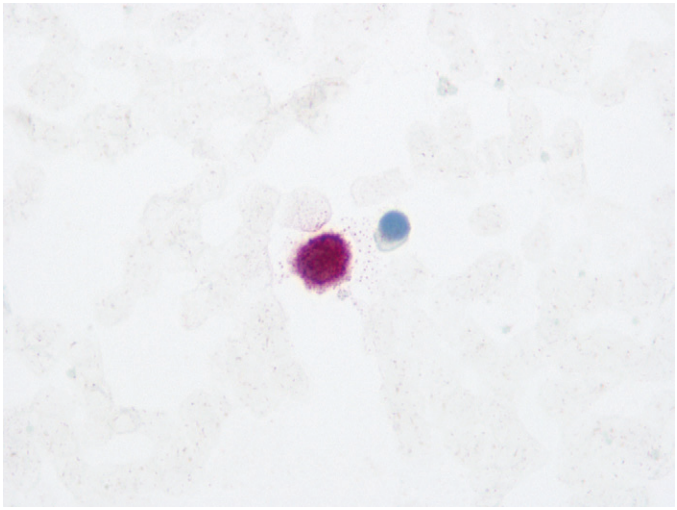

Figure 77-5 BONE MARROW ASPIRATE SMEAR (TRAP STAIN ×1000). *(Provided by Jeffrey Jorgensen, Department of Hematopathology, UTMDACC.)*

Splenic enlargement is present in the majority of patients and can be massive in about 20%. Splenic involvement is characterized by diffuse infiltration of the red pulp cords and sinuses, with atrophy and replacement of white pulp. Blood-filled sinuses lined by hairy cells (often referred to as *pseudosinuses* or *red blood lakes*) are often a prominent but not pathognomonic finding (Fig. 77-6).[1] Significant lymphadenopathy is uncommon and present only in the advanced stages of the disease. When involved, the lymph node enlargement is largely confined to the abdominal and retroperitoneal nodes. The infiltrates are distributed in the interfollicular and paracortical areas of the nodes and may extend through the capsule to the surrounding adipose tissue. Hepatomegaly is much less frequent, occurring in up to a third of patients. However, the liver is almost always involved with a mononuclear cell infiltrate in the sinusoids, portal areas or both. Unusual sites of disease involvement have been reported, including mediastinal and paravertebral masses, skeletal lytic lesions, pleural effusions and ascites, as well as involvement of skin, eye, the central nervous system, and the gastrointestinal tract. Other notable clinical features include a predisposition to infections and an uncommon association with autoimmune disorders such as polyarteritis nodosa, vasculitis, and rheumatoid arthritis.

Several cytogenetic abnormalities have been reported in HCL but no single abnormality is present consistently. Few cytogenetic studies have been reported because of the rarity of the disease, difficulty in obtaining marrow samples, and low responsiveness of hairy cells to common mitogens. In the reported series, chromosomes 1, 2, 5, 6, 11, 14, 19, and 20 are most frequently involved, with chromosome 5 and 14 abnormalities predominating. Deletions and mutations of p53, as well as overexpression of cyclin-D1, have been reported. Lack of reciprocal chromosomal translocations in HCL is consistent with a memory B-cell origin of the disease, because these translocations are thought to arise from mistakes in the immunoglobulin remodeling mechanisms, which are believed to be turned off in memory B cells.[2]

DIFFERENTIAL DIAGNOSIS

HCL must be distinguished from other indolent lymphoid neoplasms, such as B-prolymphocytic leukemia and SMZL, and most notably, from HCLv, the variant form of the disease. HCLv is a rare disorder accounting for approximately 10% of cases and occurring

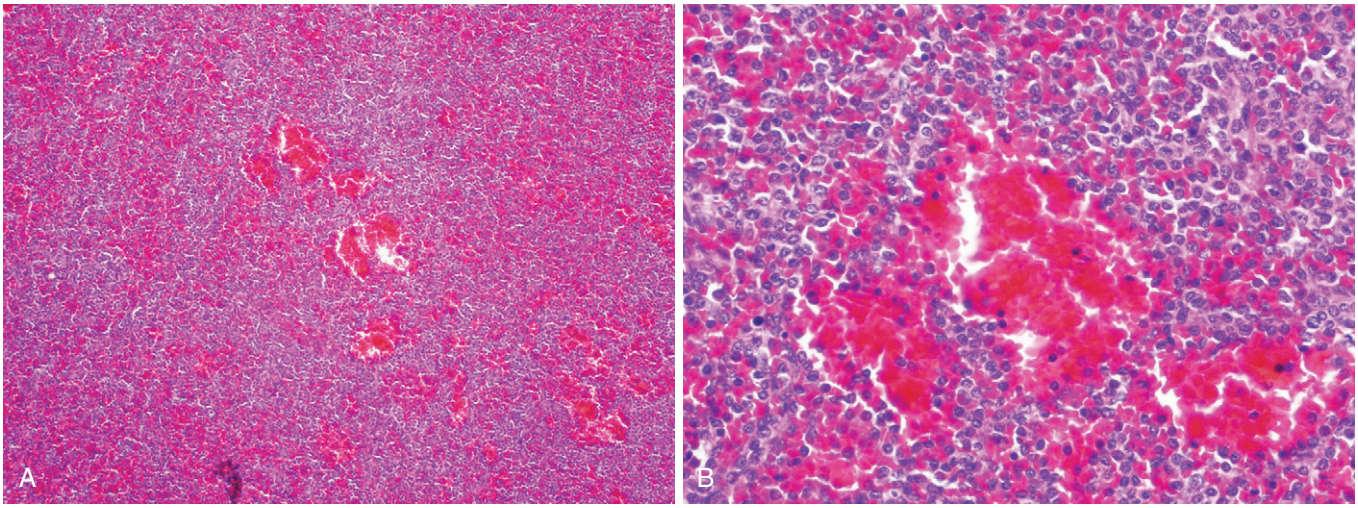

Figure 77-6 PATHOLOGIC FINDINGS IN THE SPLEEN. **A,** H&E stain (×100). **B,** H&E stain (×400). *(Provided by Roberto Miranda, Department of Hematopathology, UTMDACC.)*

Table 77-2 Immunophenotype of Hairy Cell Leukemia and Other Indolent Lymphoid Neoplasms

Disease	sIg	CD5	CD10	CD11c	CD20	CD22	CD23	CD25	CD103
HCL	+/–	–/+	–	++	+	+	–/+	+	++

B-PLL	++	+	–	–/+	+/–	+	+/–	–	–
HCLv	+/–	–	–	++	+	+	–	–	–/+
MCL	+	++	–	–	+	+	–/+	–	–
SMZL	+	–/+	–/+	+	+	+/–	–/+	–	–
FL	+	–	+	–	++	+	–/+	–	–

in the older population, with the median age being 71 years.[8] There are no reports of an association with exposure to carcinogens, radiation, or viral infections, and no specific underlying cause has been described. Patients often have an elevated WBC count (>10 × 10^9/L) including atypical hairy cells with prolymphocytic features and lack monocytopenia. Splenomegaly and cytopenias are present in the majority of patients, and the pattern of bone marrow and splenic involvement is similar to HCL and different from prolymphocytic leukemia and SMZL. The immunophenotypic expression of various lymphoid markers is also different in these disorders, with HCLv lacking CD25 expression, further assisting diagnosis (Table 77-2). Another aid in distinguishing HCL from HCLv is CD123 expression, which is positive in the former and negative in the latter. A number of chromosomal abnormalities, including translocations, have been reported in a few cases. Although HCLv has some similarities to HCL, the two conditions differ in a number of features, most notably being HCLv's lack of responsiveness to classic HCL therapies. As such, it is important to distinguish the two and consider them as separate diseases. HCL and HCLv have different immunoglobulin heavy (IGH) chain gene repertoires and somatic hypermutation patterns.[4] A recent report also suggested that high expression levels of AICD can distinguish HCL from HCLv, as well as from SMZL. However, the same group was unable to find distinct cytogenetic events to distinguish HCL from its variant, using high-resolution genomic profiling. Most recently, *BRAF* V600F mutations have been shown to occur exclusively in HCL samples and not in those from patients with HCLv and SMZL.

SMZL (previously referred to as *splenic lymphoma with villous lymphocytes [SLVL]*) exhibits some of the clinical and morphologic features of HCL but typically has a more prominent peripheral blood involvement, lacks TRAP expression, and has a different immunophenotype, including absence of expression of CD25 and CD103. HCL should be distinguished from other indolent lymphoid neoplasms such as chronic lymphocytic leukemia, prolymphocytic leukemia, and follicular lymphomas, but this distinction is typically easily made using the characteristic morphologic and immunotypic findings characteristic of these disorders (Table 77-2). Other disorders that should be included in the differential diagnosis include aplastic anemia, primary myelofibrosis, and systemic mast cell disorders.

TREATMENT

Indications for Therapy

HCL has an indolent course, with some patients surviving many years without receiving therapy and others not requiring further therapy despite persistence of residual morphologic evidence of the disease after the initial treatment.[9] Therefore a watch-and-wait strategy may be appropriate in the initial management of patients with limited or no manifestations of the disease. Disease progression that necessitates therapy is commonly evident by the development of progressive cytopenias and their associated complications, such as infections, bleeding, and progressive fatigue. No specific criteria for therapy have been established, but generally treatment is indicated when the patient has significant cytopenias, symptomatic organomegaly or adenopathy, infections, or constitutional symptoms such as fever, night sweats, or fatigue. Typical blood counts warranting therapy include an absolute neutrophil count < 1.0 x 10^9/L, a platelet count < 100 X 10^9/L, and/or a hemoglobin < 12.0 g/dL.

Historic Aspects of Therapy

Progress in the treatment of patients with HCL over the last 25 years has been significant, with survival curves now approaching those of age-matched cohorts without the disease. Before the introduction of interferon-α, splenectomy was used effectively to treat patients with HCL. Although splenectomy does not result in morphologic remissions in the bone marrow, the peripheral blood counts are normalized in up to 70% of patients. Progression of disease can be expected in about 45% within 5 years. Furthermore, there is an associated morbidity and mortality with the procedure. As such, splenectomy is no longer performed in this disease except in rare, selected patients.

The first report of effective treatment of HCL with interferon-α described several patients with progressive disease who received daily doses of 3 million units. Three patients achieved complete response (CR) with the other four having partial responses (PR). The activity of interferon-α in HCL was further confirmed by several large trials reporting CR rates of 4% to 30% and PR rates of 43% to 86%. Even in patients achieving a CR, careful morphologic examination of the bone marrow revealed residual hairy cells. With further follow-up of patients treated with interferon-α, it is clear that a significant proportion will relapse and require further therapy. However, the same authors reported that a number of patients remaining alive after a 10-year follow-up had not required further therapy with interferon. The median failure-free survival reported by these and other investigators ranges from 6 to 25 months. A number of predictors of outcome have been evaluated, with expression of CD5 reported as a predictor of poor response.

The precise mechanism of action of interferon-α in HCL is unknown and may be related to the reduced production of a number of cytokines such as granulocyte colony-stimulating factor (GCSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin-3 (IL-3), and interleukin-6 (IL-6). Others have demonstrated that interferon-α can mediate apoptosis of hairy cells through the effects of tumor necrosis factor-α (TNF-α).

Treatment with interferon-α is associated with significant toxicity including flu-like symptoms, anorexia, fatigue, nausea and vomiting, diarrhea, skin rash, peripheral neuropathy, and central nervous system dysfunction (such as depression and memory loss). This and the introduction of nucleoside analogs that are generally more effective in achieving responses has led to the use of interferon being limited to rare cases and special circumstances.

Purine Nucleoside Analogs

Although there are no specific guidelines for the treatment of HCL, monotherapy with cladribine or pentostatin is the current established standard. Furthermore, despite the lack of a comparative study, a substantial number of data suggest that both drugs are equally effective in terms of response rate and durability.[10] The use of nucleoside analogs in treating lymphoid neoplasms can be traced back to the observation that children with the deficiency of the enzyme adenine deaminase (ADA) developed severe combined immunodeficiency (SCID). The accumulation of the triphosphorylated form of deoxyadenosine (dependent on the action of the enzyme deoxycitidine kinase [DCK]) is thought to be responsible for the lack of lymphocyte development. Similarly, after treatment with purine nucleoside analogs, the accumulation of deoxyadenosine triphosphate results in DNA strand breaks, inhibition of DNA repair, and apoptosis preferentially in lymphoid cells, rich in DCK and low in 5′ nucleotidase (the enzyme responsible for degrading deoxyadenosine monophosphate).

Cladribine is a purine nucleoside analog resistant to deamination by ADA. It accumulates in lymphocytes rich in DCK and inhibits ribonucleotide reductase, impairing DNA synthesis and repair. Cladribine has been very effective for the initial therapy of HCL, with overall response rates ranging from 75% to 100% after a single course of the drug (Table 77-3). Piro and colleagues first reported 12 patients with HCL who received cladribine 0.1 mg/kg per day by intravenous continuous infusion for 7 days.[11] Eleven patients achieved CR, and one had PR.[11] Since then, other dose, routes of administration, and schedules of the drug have been used effectively (Tables 77-3 and 77-4). Weekly administration was evaluated in severely neutropenic patients in a pilot study in an effort to produce a less toxic strategy.[12] The authors reported a 73% CR rate, with an overall response rate of 100%. However, only 16% developed severe neutropenia and 8% infections.[12] In a more recent report, 132 patients with untreated HCL were randomized to receive cladribine either on 5 consecutive days or a novel schedule of 6 weekly doses.[13] The response rates, overall response rates, progression free, overall survival, and incidence of grade 3 and 4 infections were the same in the two arms.[13] The subcutaneous route was also evaluated after the initial demonstration that similar plasma levels to those seen with the intravenous route can be achieved subcutaneously. Juliusson and colleagues treated 73 patients with cladribine administered as a subcutaneous daily injection for 7 days and reported a CR rate of 81% after 1 (75%) or 2 courses.[14]

Despite the very high response rate to cladribine, responses are not universal and a significant proportion of patients relapse. Saven and colleagues reported the long-term outcome of 358 patients with HCL who were followed for a median of 52 months.[15] Of these patients, 26% relapsed after a median of 29 months.[15] The same group reported on 209 patients treated with cladribine with a follow-up period of at least 7 years.[16] Although the overall response rate was 100%, 76 (37%) patients relapsed after their first course of cladribine with a median time to relapse of 42 months.[16] Notably, the time to treatment failure curve did not show a plateau, indicating that the treatment is probably not "curative."[16] Outcome of patients achieving CR with their initial therapy is better than those achieving PR (Fig. 77-7). More recent publications have confirmed the high response rate of patients with HCL treated with cladribine and have provided long-term follow-up data.[17] Jehn and colleagues described a 12-year follow-up of 44 patients (including 11 with prior therapy before receiving cladribine) who received cladribine at the originally reported dose and schedule. The CR rate was 98%, and with a median follow-up of 8.5 years (range 0.1 to 12.2), 17 patients had relapsed. Eight of nine patients retreated with cladribine responded again. The overall survival at 12 years was 79%. Zinzani and colleagues reported the long-term outcome of 37 patients treated with one of two regimens of cladribine. Twenty-one patients received cladribine by a 2-hour infusion for 5 days, whereas 16 patients were treated with a once-weekly schedule for 5 weeks. A CR rate of 81% with an overall response rate of 100% was reported, with no difference between the two schedules. After a median follow-up of 122 months (range 54 to 156), the overall relapse rate was about 30% for both groups. The projected 13-year overall and relapse-free survival rates were 96% and 52%, respectively. Investigators at Northwestern University treated 86 consecutive patients with cladribine and reported a CR rate of 79%, as well as a PR rate of 21%.[17] The progression-free survival after 12 years was 54%. After a median follow-up of 9.7 years (range 0.3 to 13.8), 31 patients (36%) relapsed.[17] Of these, 23 were treated with a second course of cladribine; 12 (52%) achieved CR, and 7 (30%) achieved PR. The overall survival after 12 years was 87%.[17] The authors suggested that the lower CR rate in this study was due to their more stringent criteria for response, which included a requirement for resolution of splenomegaly and lymphadenopathy by CT scan as criteria for CR.[17]

Similar excellent responses have been achieved using pentostatin (Table 77-5). Overall CR rates of 44% to 89% have been reported with pentostatin administered intravenously at a dose of 2 to 4 mg/m² every 2 weeks. Spiers and colleagues were the first to report that a nucleoside analog (pentostatin) was capable of producing CRs in patients with HCL. The activity of pentostatin in HCL was confirmed in a number of larger studies by several investigators. Grever and colleagues conducted a large, randomized clinical trial comparing pentostatin with interferon-α in patients with previously untreated HCL.[18] Patients were randomized to receive either IFN-α 3 million

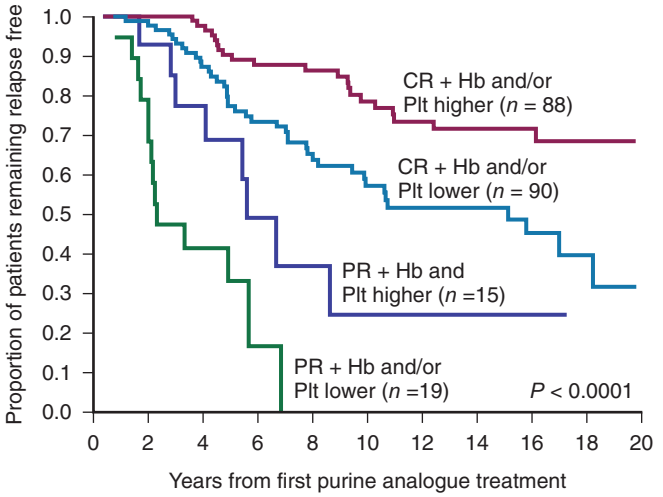

Figure 77-7 LONG-TERM FOLLOW-UP OF PATIENTS TREATED WITH NUCLEOSIDE ANALOG MONOTHERAPY. Excellent outcome for the majority, and significantly better relapse-free survival for patients achieving CR versus PR with initial therapy. *(Else M, Dearden CE, Matutes E, et al: Long-term follow-up of 233 patients with hairy cell leukaemia, treated initially with pentostatin or cladribine, at a median of 16 years from diagnosis.* Br J Haematol *145:733, 2009.)*

units subcutaneously three times per week or pentostatin 4 mg/m^2 intravenously every 2 weeks.[18] Patients who did not respond to initial treatment were crossed over. Confirmed complete and overall response rates were reported for 76% and 79% of patients treated with pentostatin, respectively, as compared with 11% and 38% of those treated with interferon-α.[18] Response rates were significantly higher (P <0.0001), and relapse-free survival was significantly longer with pentostatin than with interferon (P<0.0001).[18] Furthermore, patients who were initially assigned to receive interferon were frequently crossed over to pentostatin therapy, achieving a CR rate of 66%. In a follow-up report, Flinn and colleagues described the long-term outcome of 241 patients who were treated with pentostatin either as initial therapy or after failure of IFN-α.[19] The 5- and 10-year event-free survival rates were 85% and 67% respectively (Fig. 77-8). Other investigators have reported long-term follow-up data on patients treated with pentostatin. Maloisel and colleagues reported outcome of 230 evaluable patients with HCL treated with pentostatin, including 84 with pentostatin as the initial agent. They reported a CR rate of 79%, with an overall response rate of 96%. With a median follow-up of 63.5 months, 34 (15%) of 220 responding patients had relapsed. The estimated 5- and 10-year disease-free survival was 88% and 69%, respectively, and the estimated 5-year overall survival was 89%.

There are no prospective trials comparing the efficacy and durability of response between cladribine and pentostatin. Dearden and colleagues examined the outcome of the patients with the two agents at their institution and reported that 82% of 165 patients treated with pentostatin achieved a CR compared with 84% of 45 patients treated with cladribine. Relapse rates were 24% with pentostatin and 29% with cladribine after median follow-up of 71 and 45 months, respectively. They suggested a longer remission duration with pentostatin. However, with further follow-up, there appears to be no difference between the two agents with regard to disease-free survival (Fig. 77-9, *A*). Further follow-up data of these cohorts of patients have been reported.[10] With a median follow-up of 16 years, there was no significant difference in the outcome of the patients treated with the 2 drugs. After relapse or nonresponse, patients could be successfully retreated with pentostatin or cladribine but achieved lower response rates, with a decline in the proportion of patients achieving CR with second- and third-line therapy (Fig. 77-9, *A*).[10] However, CRs were equally durable after first, second, or third line of treatment. Complete responders and those with pretreatment hemoglobin >10.0 g/dL and platelet count >100 × 10^9/L had the longest

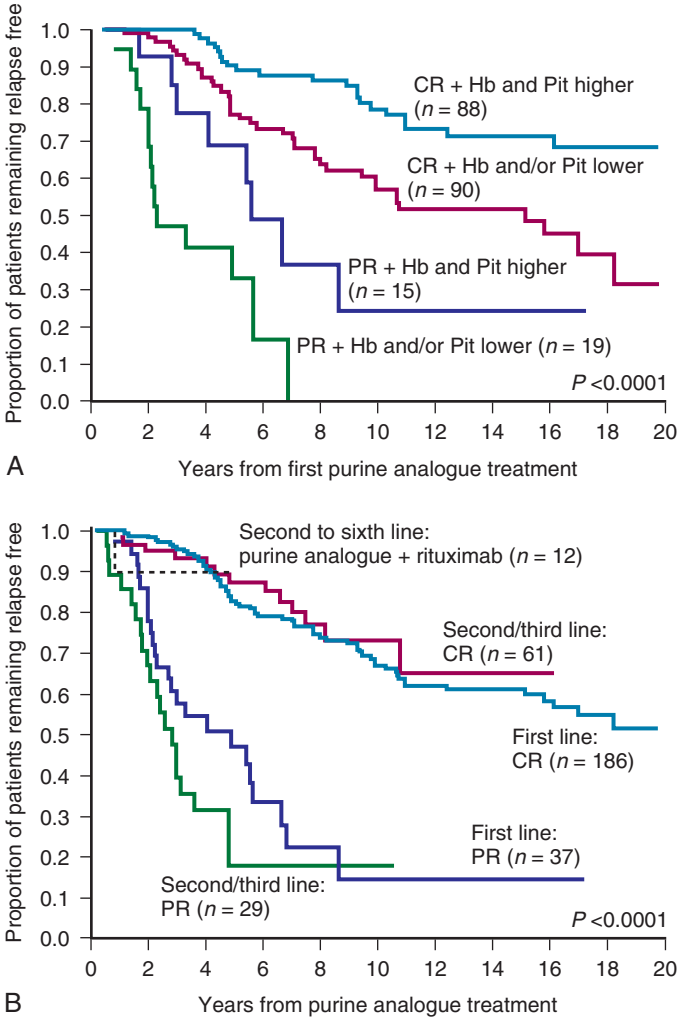

Figure 77-10 A, Relapse-free survival after initial therapy with nucleoside analogs by initial response and blood counts. **B,** Relapse-free survival analyzed by line of therapy and response to treatment. Complete responses were equally durable, whether achieved at first-, second-, or third-line single-agent treatment. *(Else MA, Ruchlemer R, Osuji N, et al: Long remissions in hairy cell leukemia with purine analogs.* Cancer *104:2442, 2005; and Else M, Dearden CE, Matutes E, et al: Long-term follow-up of 233 patients with hairy cell leukaemia, treated initially with pentostatin or cladribine, at a median of 16 years from diagnosis.* Br J Haematol *145:733, 2009).*

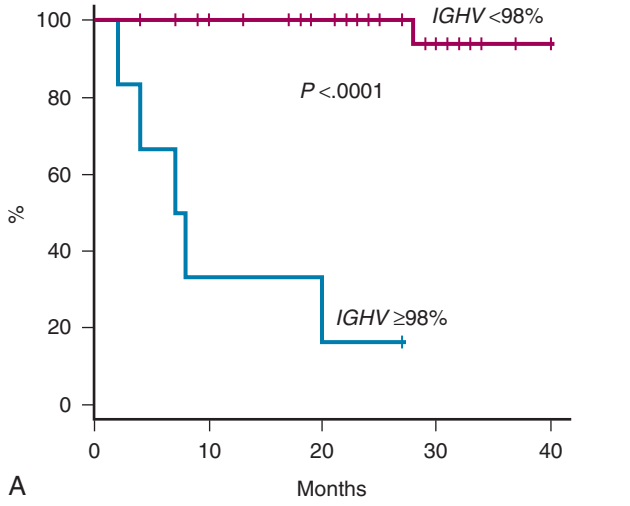
relapse-free survival (p <0.0001) (Fig. 77-10).[10] Patients who were in CR after 5 years had only a 25% risk for relapsing by 15 years.[10] These data suggest that both pentostatin and cladribine are highly effective in treating patients with HCL but not curative in all patients. Few predictors of response and long-term outcome have been reported, but the recent demonstration by two groups that patients with unmutated immunoglobulin heavy chain variable *(IGHV)* region gene were less likely to respond to cladribine suggests that further insight into the biology of the disease may potentially clarify mechanisms of resistance (Fig. 77-11).[20-21]



Monoclonal Antibodies

Several therapeutic options are now available for patients with relapsed HCL. The efficacy of the monoclonal antibody rituximab in treating these patients has been suggested by a number of studies (Table 77-6). Rituximab is a monoclonal antibody directed against the pan–B cell antigen (CD20), which is heavily expressed on the surface of hairy cells. Nieva and colleagues reported their experience with 4 weekly doses of rituximab in 24 patients with HCL who had failed prior treatment with cladribine. The overall response rate was 26%, with 13% CR and 13% PR. No unusual toxicity was reported. Lauria and colleagues treated 10 patients with relapsed/progressed HCL with 4 weekly doses of rituximab and reported 1 CR and 4 PR (overall response rate of 50%). Hagberg and colleagues treated 11 patients with HCL (including 3 previously untreated patients) with the same regimen of rituximab for 4 weeks. The response rate was 64%, with 6 CRs and 1 PR (including 1 CR in an untreated patient). The Swiss Group for Clinical Cancer Research reported their study of 4 weekly doses of rituximab in 26 patients with relapsed/progressed HCL, showing an 80% response rate, with 32% achieving CR.

Figure 77-11 PREDICTING RESPONSE AND OUTCOME OF THERAPY WITH CLADRIBINE BY ASSESSING *IGHV* MUTATIONAL STATUS (AS WELL AS BY SPLENOMEGALY AND LEUKOCYTOSIS). *(Forconi F, Sozzi E, Cencini E, et al: Hairy cell leukemias with unmutated IGHV genes define the minor subset refractory to single-agent cladribine and with more aggressive behavior.* Blood *114:4696, 2009.)*

Thomas and colleagues used an extended regimen of rituximab 375 mg/m^2 weekly for 8 doses to treat 15 patients with relapsed/refractory HCL and reported a response rate of 80%, including 8 (52%) CR, 2 (13%) CR with residual marrow disease, and 2 (13%) PR.[22]

Rituximab has been evaluated in a sequential strategy to improve responses in patients with HCL after treatment with cladribine.[23] Rituximab has also been used concomitantly to treat patients with refractory disease with reported excellent responses suggesting a possible synergy. The investigators from the Royal Marsden NHS Trust treated 18 patients with either pentostatin ($n = 12$) or cladribine ($n = 6$) in combination with rituximab after a median of 2 (range, 1 to 6) prior treatments and reported a CR rate of 89%. Toxicity with the combination was minimal, and with a median follow-up of 36 months, all 16 patients who had achieved CR remained in CR.

Other monoclonal antibody–based therapies have developed and are under investigation. BL22 is a recombinant immunotoxin containing the variable domains of the anti-CD22 monoclonal antibody RFB4 fused to a truncated pseudomonas endotoxin A.[24] In a dose-escalation study, 16 patients who were resistant to cladribine were treated with BL22 by intravenous infusion every other day for a total of 3 doses.[24] Response included 11 CR and 2 PR. The 3 nonresponders either had preexisting neutralizing antibodies or received low doses of the immunotoxin.[24] Toxicity included a cytokine-release syndrome and development of a reversible hemolytic-uremic syndrome in 2 patients.[24] In a larger phase I follow-up study of 46 patients with previously treated CD22+ lymphoid malignancies, including 31 with HCL, 61% achieved a CR and 19% experienced a PR, further demonstrating the activity of this agent in HCL. Neutralizing antibodies occurred in 11 (24%) of 46 patients (all HCL), and a reversible hemolytic uremic syndrome

requiring plasmapheresis was observed in 1 patient with NHL during cycle 1 and in 4 patients with HCL during cycle 2 or 3. The median duration for CR was 36 months (range, 5 to 66 months). The maximum tolerated dose (MTD) was established at 40 µg/kg every other day ×3 doses. More recently, the results of a phase 2 study of the same drug in 36 patients with relapsed or refractory HCL was published.[25] Patients received BL22 at the MTD on cycle 1. Those achieving hematologic remission were observed while the others were retreated at 30 µg/kg every other day for three doses every 4 weeks beginning at least 8 weeks after cycle 1. The response after one cycle (CR, 25%; PR, 25%) improved when 56% were retreated (CR, 47%; PR, 25%).[25] A modified version of this agent, moxetumomab pasudotox (or HA22), has a superior affinity for CD22 and is under clinical development.

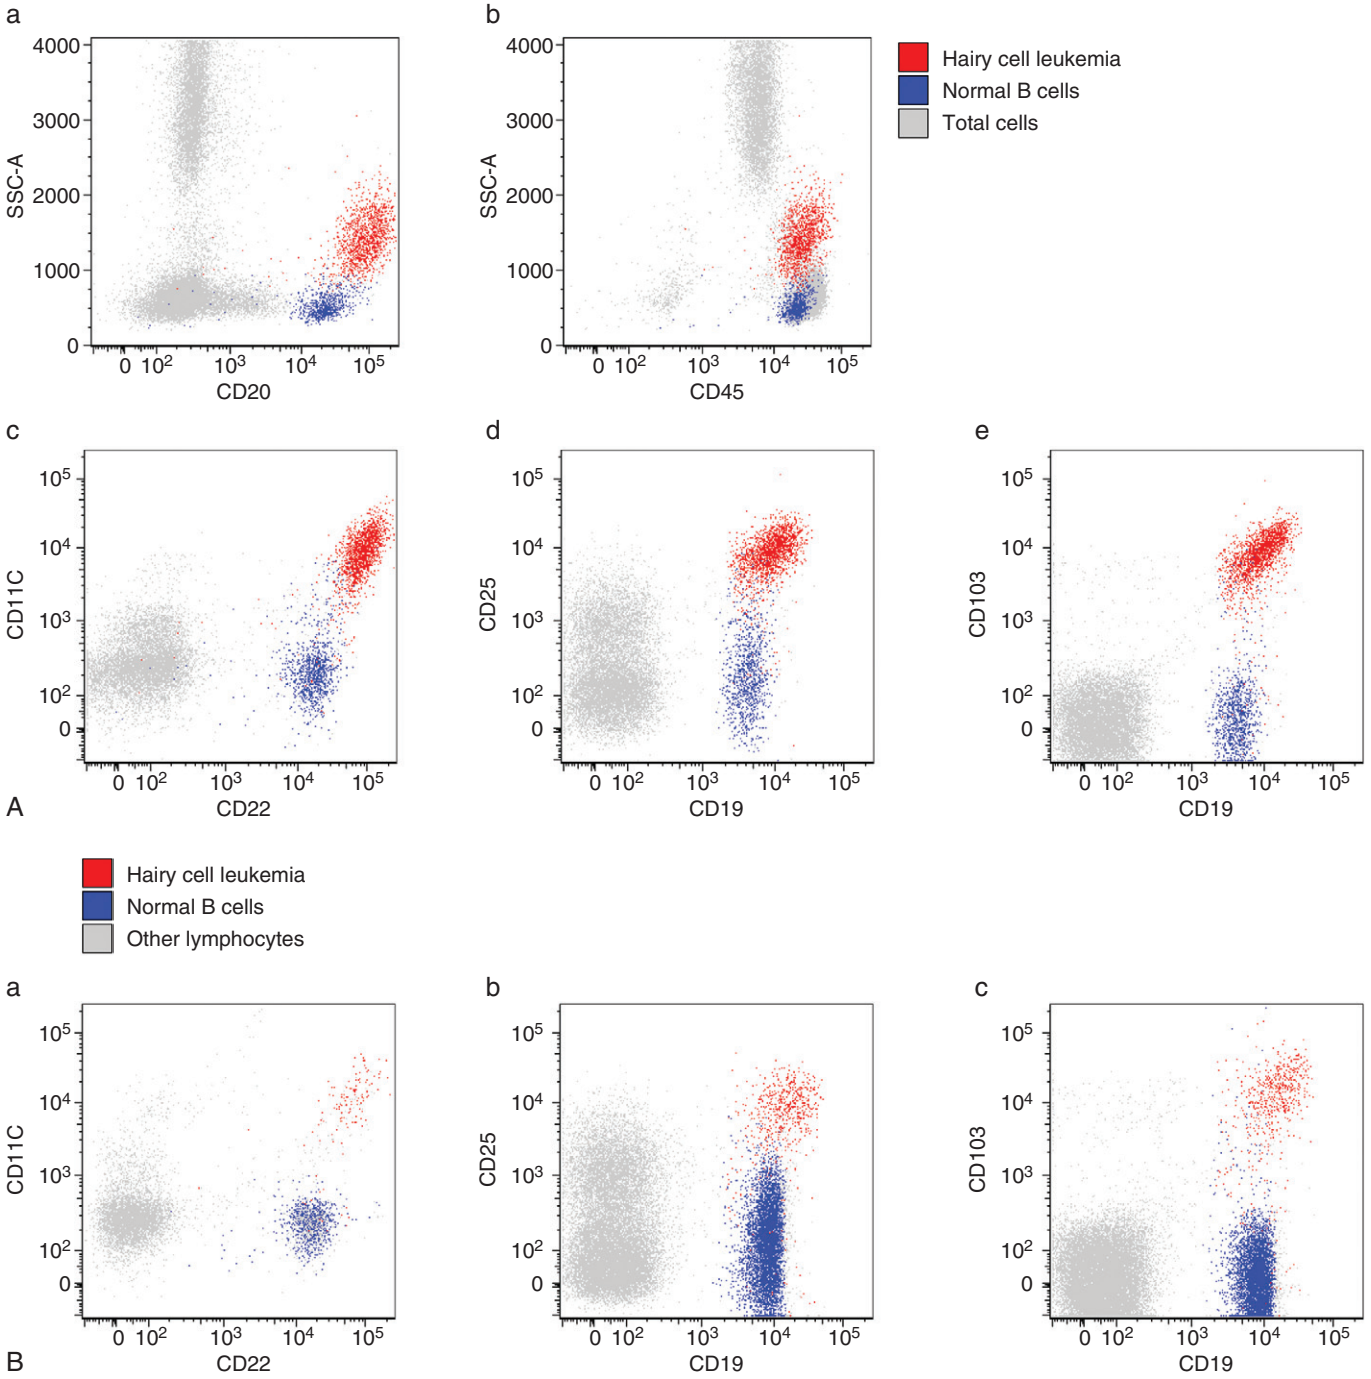

Figure 77-12 MONITORING MINIMAL RESIDUAL DISEASE IN HAIRY CELL LEUKEMIA. **A,** Total nucleated cells in a hemodilute bone marrow aspirate (*a* and *b*); total lymphocytes (*c* to *e*). Hairy cells (*red,* about 6% of total cellularity and 12% of lymphocytes) show increased side scatter (SSC) because of their high cytoplasmic complexity, compared with normal B cells *(blue).* Hairy cells often show increased expression of CD20 *(a).* On CD45 versus SSC gating plots *(b),* they may be mistaken for monocytes. Hairy cells usually show bright expression of CD11c and CD22 *(c)* and CD25 *(d)* and are positive for CD103 *(e).* **B,** Total lymphocytes from a posttherapy bone marrow aspirate, positive for minimal residual hairy cell leukemia, accounting for about 0.6% of total cellularity. Hairy cells *(red)* can be easily distinguished from normal B cells *(blue),* particularly on the basis of their bright expression of CD11c *(a)* and CD25 *(b)* and positivity for CD103 *(c).* In *a,* 30,000 total cells were collected; in *b* and *c,* 100,000. *(Courtesy Jeffrey Jorgensen, Department of Hematopathology, UTMDACC.)*

CD52 is also expressed on the surface of hairy cells, and an anecdotal report of a response to alemtuzumab has recently been published.

Minimal Residual Disease and Its Significance

Despite excellent responses, there is a definite relapse rate associated with therapy of HCL with both cladribine and pentostatin, and the relapse-free survival does not appear to plateau.[10] Wheaton and colleagues were the first to note that detection of minimal residual disease (MRD) by immunohistochemistry (using anti-CD45RO, anti-CD20, and DBA.44) in paraffin-embedded bone marrow sections of 39 patients with HCL in CR after receiving cladribine was predictive of relapse.[26] More sensitive methods of MRD detection such as immunophenotyping using multiparameter flow cytometry, as well as analysis of antigen receptor genes by polymerase chain reaction (PCR) using consensus or clone-specific primers, have been evaluated recently and can be used to monitor the disease course (Fig. 77-12).[23,27,28] Other markers of the disease, such as serum-soluble CD25, CD22, and CD307, have been evaluated and shown to be reliable for disease monitoring.[29]

Rituximab has been evaluated for eradication of MRD assessed by flow cytometry and consensus primer PCR; whether such elimination of MRD can translate to a longer relapse-free survival is unclear.[9,23] Sigal and colleagues reported that patients with HCL may harbor MRD and even morphologically evident disease many years after initial therapy without experiencing overt relapse, raising the question of whether eradication of MRD should be the goal of therapy in HCL.[9] However, several studies have suggested that patients who achieve a morphologic CR have a better outcome than those with lesser responses. Whether this can be extrapolated to complete eradication of detectable disease remains to be established.

Treatment of Disease Relapse

Despite the success of the nucleoside analogs in achieving generally durable responses in the majority of patients, they are not considered to be curative, with about 40% of patients relapsing by 10 years after treatment.[10] Second and third courses of nucleoside analogs have been used, either with the same or the alternate agent used to treat relapsing disease. However, CRs are less frequent with subsequent courses. Because a single course of cladribine or pentostatin can suppress $CD4^+$ lymphocytes for a substantial period of time, concerns about the use of multiple courses of these agents have been raised.[30]

Rituximab has the advantage of sparing T-lymphocytes and has shown significant activity in patients with relapsed disease (Table 77-6). However, the overall response rate is relatively low, particularly in studies using only 4 weekly doses of rituximab. Immunotoxins such as BL22 and HA22 have been studied in cases of relapsed disease, produce high responses, and have limited toxicity; however, they are not, as yet, widely available. Bendamustine, a novel molecule with structural features of both an alkylating agent and a purine nucleoside analog, has been used by one group for the treatment of relapsed and refractory disease. Anecdotal reports have circulated about the use of other agents such as alemtuzumab.

Incidence of Second Malignancies

Early studies suggested an association between HCL and development of second malignancies, but this link is controversial and has been refuted by other reports. The reported second cancers include melanoma, prostate cancer, gastrointestinal cancers, and non-Hodgkin lymphomas. Whether these second malignancies are related to the primary disease itself or to its treatment has also been debated. A number of long-term studies of patients treated with pentostatin or cladribine have not shown a statistically significant increased risk for second malignancies. It remains unclear whether the immunosuppressive effects of nucleoside analogs play a role in such susceptibility to developing a second malignancy or whether disease-related factors or perhaps increased monitoring of these patients are important.

FUTURE DIRECTIONS

Over the past decade, success in the treatment of HCL had led to diminished interest in developing new therapeutic strategies for treating this uncommon leukemia, with research confined to a few specialized centers interested in the biology and pathogenesis of this disease. Recent reports unraveling the biologic and molecular aspects of the disease have kindled a significant resurgence of interest.[2] Further studies into other aspects of the disease, such as the role of microenvironment, B-cell receptor signaling, and the complex interaction of various signaling pathways will likely provide better therapeutic tools and strategies.[2]

CHAPTER 78

CLINICAL MANIFESTATIONS AND TREATMENT OF MARGINAL ZONE LYMPHOMAS (EXTRANODAL/MALT, SPLENIC, AND NODAL)

Carlos A. Ramos

The term *marginal zone* refers to a histologic compartment located at the periphery of lymphoid follicles immediately outside their mantle zone.[1] The marginal zone is especially evident in the spleen, although identical areas have been observed in other lymphoid structures, including mesenteric lymph nodes and mucosa-associated lymphoid tissue (MALT) (Fig. 78-1).[2] Ordinarily, it is composed predominantly of B cells that are slightly larger than mantle zone lymphocytes and strongly positive for surface IgM, but weakly positive for IgD (in contrast to mantle zone cells, which are strongly positive for IgD).[3] Marginal zone B lymphocytes are thought to be involved in fast protective responses against pathogenic encapsulated bacteria that do not trigger classical T cell–dependent humoral immunity.[4] They are also assumed to be the physiologic counterpart of a group of non-Hodgkin lymphomas (NHL) that are currently referred to as *marginal zone lymphomas (MZLs).*

Although MZLs share a common denomination, arising from histologic similarities, new genetic findings and longer follow-up studies have established that the currently recognized subtypes of MZLs, initially described in the Revised European-American Lymphoma (REAL) classification, are different diseases.[5] In the most recent WHO classification of tumors of the hematopoietic and lymphoid tissues,[6] these disorders comprise three distinct entities: extranodal MZL of MALT type (ENMZL), splenic MZL (SMZL) and nodal MZL (NMZL). Immunoproliferative small intestinal disease (IPSID), formerly known as alpha heavy chain (or Seligmann) disease, has been recently recognized as a variant of ENMZL.[7] In aggregate, MZLs represent approximately 10% of all NHL.[8] Clinically, they behave indolently and have a prolonged course. Therefore, management strategies share similarity with other low-grade lymphomas,[9] although specific biologic characteristics and particular pathophysiologic mechanisms determine unique therapeutic approaches in some of the subtypes. This chapter will summarize the clinical characteristics and current management strategies for the different types of MZL.

INITIAL EVALUATION OF MARGINAL ZONE LYMPHOMA

As for other lymphomas, biopsy of an adequate amount of tissue with review by a hematopathologist with expertise in the field is essential to establish the diagnosis. Excisional or incisional biopsies of a lymph node or suspicious mass, obtained by endoscopic or conventional means, are preferred. In patients without easily accessible nodes or masses, computed tomography (CT) or ultrasound-guided core needle biopsy is usually well tolerated and may be adequate for diagnosis. Fine-needle aspiration is not appropriate for diagnosis; sufficient material must be obtained for proper histologic examination and required immunophenotypic and genetic studies.

Physical examination with special attention to peripheral lymph nodes and the abdomen should be performed. Initial laboratory evaluation should include a complete blood count (cytopenias may be evidence of marrow infiltration or of autoimmunity) with evaluation of a peripheral blood smear (to exclude leukemic involvement) and basic biochemical studies, including lactate dehydrogenase (LDH) level, which is an important prognostic factor and a potential indicator of transformation from indolent to aggressive lymphoma. Serum protein electrophoresis and immunofixation may demonstrate a monoclonal immunoglobulin. β_2-microglobulin levels may have prognostic value[10] as in other indolent lymphomas.

Depending on the primary site of disease, specific procedures may be indicated. Gastrointestinal MZLs may require repeat staging endoscopies, during which an adequate number of biopsies should be obtained. For gastric ENMZL, the European Gastro-Intestinal Lymphoma Study (EGILS) group recommends a mapping procedure with a minimum of 10 biopsies taken from visible lesions and additional ones from macroscopically normal mucosa; the same procedure should be repeated to assess treatment response.[11] Since endoscopic biopsies are not transmural, endoscopic ultrasound (EUS) is a useful way to assess the depth of involvement, which has prognostic implications.[12-17] For head primaries, such as ocular adnexal ENMZL, appropriate directed examination and imaging studies (CT or magnetic resonance) are indicated.

STAGING OF MARGINAL ZONE LYMPHOMA

Imaging studies of the chest, abdomen, and pelvis, usually CT scans, should be obtained to adequately stage the disease. PET scan has been increasingly used for staging and evaluation of response to therapy in NHL, but it may be less useful in MZL because up to 60% of these lymphomas may be PET-negative, especially in early-stage gastric ENZML.[18] Some MZL series, however, document a PET-positivity rate of up to 80%.[19-23] Also for staging and, occasionally, for diagnostic purposes, bone marrow biopsy and aspirate are usually advocated, even in cases in which the likelihood of systemic disease is low, because any positive result has important implications for therapy.

Staging of MZL is similar to that of other lymphomas; the Ann Arbor system, or an adapted version,[24] is used most frequently (Table 78-1). Nonetheless, specific staging systems have been adopted for particular sites. Gastrointestinal MZL is often staged according to a modified Ann Arbor scheme, commonly known as the Lugano staging system,[25] which incorporates indices corresponding to depth of mucosal invasion and proximity of affected lymph nodes to the primary lesion (Table 78-1). Of note, stage IIE in the Lugano system may refer to lesions that extend by contiguity to adjacent organs and not necessarily to secondary involvement of lymph nodes. Recently, arguing that the dissemination patterns of extranodal lymphomas are essentially different from those of primary nodal lymphomas, the EGILS group has proposed a new staging system (the Paris staging system)[26] that is based on the TNM scheme used for solid tumors (Table 78-1). The International Society for Cutaneous Lymphomas (ISCL) and the cutaneous lymphoma task force of the European Organization of Research and Treatment of Cancer (EORTC) have also recently suggested a new, TNM-based staging system for cutaneous lymphomas other than mycosis fungoides and Sézary syndrome,[27] which may be used for the cutaneous forms of ENMZL (Table 78-2).

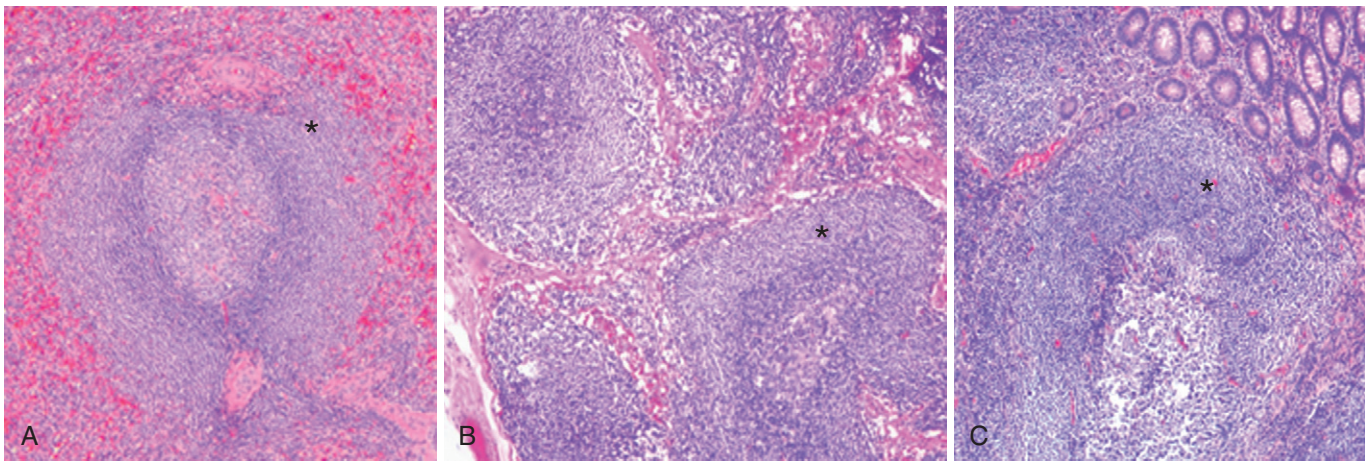

Figure 78-1 NORMAL MARGINAL ZONE CELLS. **A,** Marginal zone cells are seen most readily in sections from the normal spleen. The splenic white pulp typically has three distinctive layers: the germinal center, the mantle zone, and external to this, the marginal zone (see *asterisk*). **B,** Marginal zone cells are not usually seen in lymph nodes, but for some reason are sometimes present in mesenteric lymph nodes (see *asterisk*). They have a similar appearance to those in the spleen. **C,** In the gastrointestinal tract, the lymphoid tissue in Peyer's patches is believed to have a marginal zone equivalent (see *asterisk*). The cells are again external to the mantle zone and are believed to traffic between the epithelium and the lymphoid follicle.

Table 78-1 Staging Systems for Gastrointestinal Lymphomas

Adapted Ann Arbor System[24]	Lugano System[25]	Paris System[26]	Areas Involved*
IE1	I_1	T1 N0 M0	Mucosa to submucosa
IE2	I_2	T2 N0 M0	To muscularis propria or subserosa
		T3 N0 M0	To serosa
	IIE	T4 N0 M0	To adjacent organs
IIE1	II_1	T1-4 N1 M0	Regional lymph nodes†
IIE2	II_2	T1-4 N2 M0	Non-regional abdominal lymph nodes
IIIE	IV	T1-4 N3 M0	Extra-abdominal lymph nodes
IV		T1-4 N0-3 M1	Distant organs
		B1	Bone marrow

*In case of more than one visible lesion synchronously originating in the gastrointestinal tract, select the characteristics of the more advanced lesion.
†Anatomic designation of lymph nodes as *regional* according to site:
(a) stomach: perigastric nodes and those located along the ramifications of the celiac artery (i.e., left gastric artery, common hepatic artery, splenic artery); (b) duodenum: pancreaticoduodenal, pyloric, hepatic, and superior mesenteric nodes; (c) jejunum/ileum: mesenteric nodes and, for the terminal ileum only, the ileocolic as well as the posterior cecal nodes; (d) colorectum: pericolic and perirectal nodes and those located along the ileocolic, right, middle, and left colic, inferior mesenteric, superior rectal, and internal iliac arteries.

EXTRANODAL MARGINAL ZONE LYMPHOMA OF MALT TYPE

Epidemiology and Manifestations

ENMZL is the most frequent of the MZL subtypes, accounting for approximately 8% of all NHL.[8] The median age of presentation is around 60, with a wide range spanning from the third to the ninth decades, and there is a slight female predominance (55%).[28] In contrast to most other indolent lymphomas, ENMZL frequently presents at a localized stage (≈40% stage I and ≈30% stage II), and the risk for systemic dissemination is low (albeit variable depending on primary location), which has important implications for the choice of therapy.

The most commonly affected primary site is the mucosa of the gastrointestinal tract, in particular the stomach (approximately 44% of all ENMZL cases) followed by the small intestine (≈7%). Ocular structures are also frequently involved (≈12%), namely, the orbit (≈40% of all ocular adnexal ENMZL), the conjunctiva (35%-40%), the lacrimal glands (10%-15%) and the eyelids (≈10%).[29] Other commonly affected sites include the bronchial mucosa (≈11% of all ENMZL cases), the skin (≈9%), the salivary glands (≈6%), and the thyroid gland (≈6%). More rarely reported sites are Waldeyer pharyngeal lymphoid ring, breast, liver, pancreas, urogenital tract, and central nervous system.[30-33] Findings at presentation depend on the specific organ affected. Gastric ENMZL may lead to dyspepsia, epigastric pain, nausea, anorexia, and manifestations of gastrointestinal bleeding.[34] Conjunctival ENMZL often forms a painless nodule or plaque that has a "salmon-pink patch" appearance and can be associated with erythema, chemosis, and foreign-body sensation.[35] Primary cutaneous ENMZL frequently presents as multiple red to violaceous papules, plaques, or nodules, most often on the trunk or extremities, in particular the arms, which very uncommonly ulcerate.[36] Salivary and lacrimal gland ENMZL is often preceded by sicca syndrome, with xerostomia or xerophthalmia. B symptoms are uncommon (≈15% of cases).[30]

IPSID usually affects young adults, with no gender predominance, and is seen most commonly in the Middle East and Northern Africa, usually in low socioeconomic status populations.[37] The disease affects the proximal small bowel diffusely and generally presents with a malabsorption syndrome, with steatorrhea, hypocalcemia, weight loss, abdominal pain, and fever. Cases involving the stomach, the colon, and very rarely, the respiratory tract have been described.[7]

Pathobiology and Differential Diagnosis

Etiology

ENMZL is strongly associated with chronic antigenic stimulation, including that deriving from chronic bacterial infections[15,17,38-56] or autoimmune disorders[57-61] (Table 78-3), although the strength of this correlation for some primary sites of disease is discordant among studies, suggesting a possible geographic variation. The common assumption about this association is that continual immune stimulation by bacterial or self-antigens leads to expansion of lymphoid

Table 78-2 ISCL/EORTC Staging System for Cutaneous Lymphomas Other Than Mycosis Fungoides and Sézary Syndrome[37]

Parameter*	Description
T	
T1	Solitary skin involvement
T1a	Lesion <5 cm diameter
T1b	Lesion >5 cm diameter
T2	Regional skin involvement: multiple lesions limited to 1 body region or 2 contiguous body regions†
T2a	All-disease-encompassing in a <15-cm–diameter circular area
T2b	All-disease-encompassing in a >15- and <30-cm–diameter circular area
T2c	All-disease-encompassing in a >30-cm–diameter circular area
T3	Generalized skin involvement
T3a	Multiple lesions involving 2 noncontiguous body regions
T3b	Multiple lesions involving ≥3 body regions
N	
N0	No clinical or pathologic lymph node involvement
N1	Involvement of 1 peripheral lymph node region that drains an area of current or prior skin involvement
N2	Involvement of 2 or more peripheral lymph node regions or involvement of any lymph node region‡ that does not drain an area of current or prior skin involvement
N3	Involvement of central lymph nodes
M	
M0	No evidence of extracutaneous nonlymph node disease
M1	Extracutaneous nonlymph node disease present

*The ISCL/EORTC proposes to defer any stage groupings of the TNM classification until further information is available to validate specific stage grouping strategies.
†Definition of body regions: Head and neck: inferior border—superior border of clavicles, T1 spinous process. Chest: superior border—superior border of clavicles; inferior border—inferior margin of rib cage; lateral borders—midaxillary lines, glenohumeral joints (inclusive of axillae). Abdomen/genital: superior border—inferior margin of rib cage; inferior border—inguinal folds, anterior perineum; lateral borders—midaxillary lines. Upper back: superior border—T1 spinous process; inferior border—inferior margin of rib cage; lateral borders—midaxillary lines. Lower back/buttocks: superior border—inferior margin of rib cage; inferior border—inferior gluteal fold, anterior perineum (inclusive of perineum); lateral borders—midaxillary lines. Each upper arm: superior borders—glenohumeral joints (exclusive of axillae); inferior borders—ulnar/radial-humeral (elbow) joint. Each lower arm/hand: superior borders—ulnar/radial-humeral (elbow) joint. Each upper leg (thigh): superior borders—inguinal folds, inferior gluteal folds; inferior borders—mid-patellae, midpopliteal fossae. Each lower leg/foot: superior borders—mid-patellae, midpopliteal fossae.
‡Definition of lymph node regions: Peripheral sites: antecubital, cervical, supraclavicular, axillary, inguinal-femoral, and popliteal. Central sites: mediastinal, pulmonary hilar, paraortic, iliac.

Table 78-3 Chronic Antigenic Stimulation and Extranodal Marginal Zone Lymphoma

BACTERIAL INFECTIONS

Organism	Site	Prevalence (%)
Helicobacter pylori[15,17,39-41]	Stomach	72-100
Campylobacter jejuni[42]	Intestine (IPSID)	≈70
Chlamydophila psittaci[43-52]	Conjunctiva	0-80
Borrelia burgdoferi[53-56]	Skin	0-42

AUTOIMMUNE DISORDERS

Disease	Site	Relative Risk
Hashimoto thyroiditis*[58,59]	Thyroid	67-80
Sjögren syndrome[57,60,61]	Salivary and lacrimal glands	6.6-30.6

*Estimated by assuming cases of thyroid histiocytic lymphoma were ENMZL because these were published before the REAL classification.

elements in the connective tissue adjacent to the epithelium involved, initially leading to a process of reactive lymphoid hyperplasia. Persistent lymphocytic activation and proliferation predisposes to the accumulation of genetic errors that ultimately may result in antigen-independent growth and, consequently, lymphoma emergence.[62,63] The histologic distinction between the reactive inflammatory process associated with chronic infection (or autoimmunity) and lymphoma proper may be difficult, in which case demonstration of immunoglobulin gene monoclonality by molecular studies may aid in establishing the diagnosis of lymphoma.[64]

Histology

ENMZL is composed predominantly of morphologically heterogenous small B cells.[64] These resemble a spectrum spanning from small lymphocytes with scant cytoplasm to slightly larger cells with nuclei similar to those of centrocytes and having relatively abundant pale cytoplasm (leading possibly to a monocytoid appearance). These cells are located in the outer zone of reactive lymphoid follicles, extend into the interfollicular region and may sometimes colonize the germinal centers. Larger, immunoblast- or centroblast-like cells may be present in small numbers, but an abundance of these should raise suspicion for diffuse large B-cell lymphoma (DLBCL), which requires different management. According to the new WHO classification, the term *high-grade MALT lymphoma*, denoting the presence of sheets of transformed cells, should not be used and instead these tumors should be diagnosed as DLBCL.

Often there are lymphoid infiltrates invading and destroying glandular structures, with eosinophilic degeneration of epithelial cells (so-called lymphoepithelioid lesions), which are strongly suggestive of progression to lymphoma in cases where the differential diagnosis

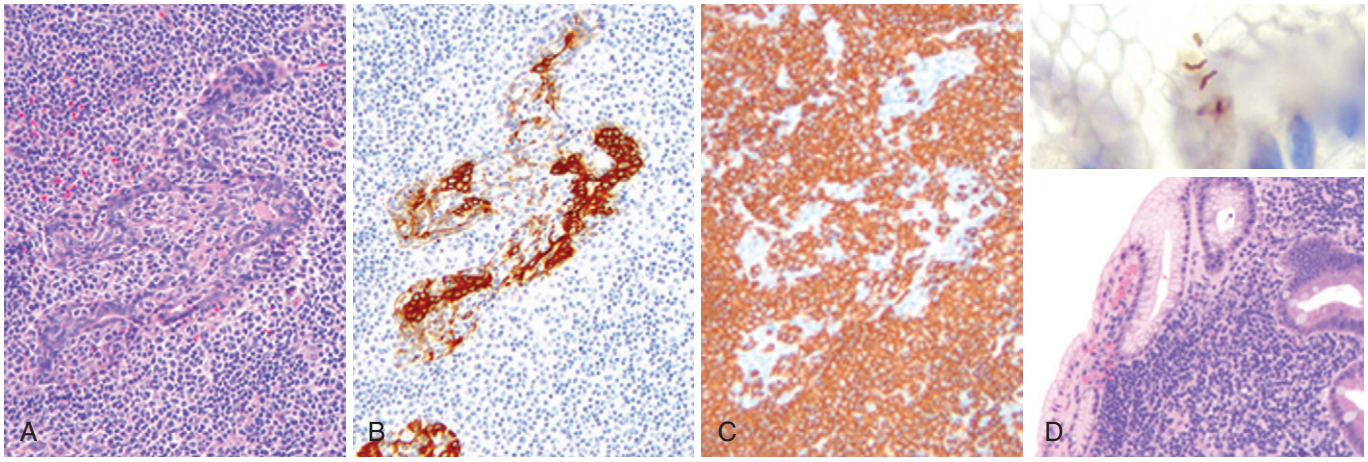

Figure 78-2 EXTRANODAL MARGINAL ZONE LYMPHOMAS OF MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT LYMPHOMAS). **A** to **C,** An example of a MALT lymphoma in the parotid gland is illustrated with various stains. The glandular tissue is overrun by lymphoid cells, which disrupt and destroy the gland. The resulting structure is referred to as a *lymphoepithelial lesion* **(A)**. These can be more clearly identified with a keratin stain **(B)** and with a B-cell stain such as CD20 **(C)**, which illustrate the glandular remnant and the B-cell proliferation. **D,** MALT lymphoma of the stomach is commonly associated with *H. pylori* infection, which can be identified by special stains *(top)*.

Table 78-4 Frequency of Common Genetic Aberrations in Extranodal Marginal Zone Lymphoma According to Primary Site of Disease

	Genetic Abnormality[31,32] Genes Involved[76]					
	t(11;18)(q21;q21)	t(14;18)(q32;q21)	t(1;14)(p22;q32)	t(3;14)(p14.1;q32)	+3*	+18*
Primary site	***API2/MALT1***	***IGH@/MALT1***	***IGH@/BCL10***	***IGH@/FOXP1***	***NFKBIZ, BCL6, FOXP1, ...***	***BCL2, NFATC1, ...***
Lung	36-53	6-10	2-7	0	20	7
Intestine (non-IPSID)	13-56	0	0-13	0	75	25
Stomach	6-26	1-5	0	0	11	6
Ocular adnexa	3-10	0-25	0	0-20	38	14
Salivary glands	0-5	0-16	0-2	0	55	19
Skin	0-4	0-14	0	0-10	20	4
Thyroid	0-17	0	0	0-50	17	0

All values expressed as percentages of cases.
*Mostly partial trisomies. Data summarized based on references noted.

with reactive lymphoid hyperplasia is in doubt (Fig. 78-2). Plasmacytic differentiation is frequent, especially in association with cutaneous, thyroid, and intestinal (IPSID) ENMZL and may pose differential diagnosis problems with lymphoplasmacytic lymphoma. These plasmacytoid cells often contain periodic acid–Schiff (PAS)–positive inclusions, known as Dutcher or Russell bodies, depending on whether they are located over the nucleus or in the cytoplasm, respectively.[65]

In gastric ENMZL, histology also plays an important role in establishing the diagnosis of *Helicobacter pylori* infection. All biopsy samples should have sections appropriately stained for its detection (see Fig. 78-2, *D*). Because proton pump inhibitors (PPIs) may decrease the sensitivity of detection, patients should stop taking these medications for at least 2 weeks before biopsies are obtained.[66,67]

Immunophenotype

ENMZL cells display common pan B-cell markers, such as CD19 and CD20. They are also usually positive for the complement receptors CD21 and CD35, antigens that are shared with follicular dendritic cells, and also for CD79a. Plasmacytoid cells can be CD138-positive. Helpful in the differential diagnosis with other indolent lymphomas, ENMZL are usually CD5-negative (in contrast to chronic lymphocytic leukemia/small lymphocytic lymphoma [CLL/SLL] and mantle cell lymphoma [MCL]), CD23-negative (in contrast to CLL/SLL), CD10-negative (in contrast to follicular lymphoma [FL]), and cyclin D1-negative (in contrast to MCL). They are also negative for BCL6, which may be helpful to exclude transformation to DLBCL. Except for IPSID, in which tumor cells express a truncated alpha heavy chain without any light chain, most ENMZL are typically positive for IgM or, less commonly, IgA or IgG, with light chain restriction. IgD expression is usually negative or very weak. These immunoglobulins may be secreted, especially when there is significant plasmacytic differentiation, and can give rise to a monoclonal band in the serum protein electrophoresis. The truncated heavy chains of IPSID usually do not appear as a monoclonal band because they co-migrate with other serum proteins but can be detected with anti-alpha heavy chain antibodies on immunofixation.

Genetics

Specific chromosomal aberrations have been associated with ENMZL, the frequency of which depends strongly on the primary site of disease (Table 78-4).[31,32] These abnormalities can be detected by

conventional cytogenetics in metaphase plates or through fluorescent in situ hybridization (FISH) of interphase nuclei using specific probes. The most commonly observed abnormality is the t(11;18)(q21;q21), which fuses the API2 (apoptosis inhibitor-2 protein) and MALT1 (MALT lymphoma translocation-1 protein) genes in chromosomes 11 and 18, respectively, leading to expression of an API2-MALT1 chimeric protein.[68] The native MALT1 is part of a protein complex that includes the BCL10 protein (B-cell lymphoma protein 10) and that indirectly leads to nuclear factor kappa-B (NFκB) activation, a process under strict control by several upstream factors. Expression of the fusion protein leads to constitutive activation of NFκB via canonical[69] and noncanonical[70] pathways, which in turn leads to resistance to apoptosis and uncontrolled proliferation. The t(11;18) has a special prognostic significance in gastric ENMZL, because its presence is associated with worse response to antibiotherapy,[71] which is at least partly due to its higher prevalence in *H. pylori*–negative gastric ENMZL.[72]

Another, less frequently observed, abnormality is the t(14;18)(q32;q21). This translocation is different from that observed in follicular lymphoma, which involves the BCL2 gene, and instead brings the MALT1 gene under the influence of the immunoglobulin heavy chain gene promoter (IGH@), leading to overexpression of MALT1 and, through mechanisms akin to those of t(11;18), constitutive activation of NFκB. The t(1;14)(p22;q32) is seen even more rarely and causes overexpression of the BCL10 gene, which is placed under control of the IGH@ promoter, and, in turn, activation of the same pathways affected by MALT1. A fourth translocation, t(3;14)(p14.1;q32), described mostly in ocular, cutaneous, and thyroid ENMZL, involves the FOXP1 (forkhead box protein P1) transcription factor and the heavy chain promoter.[73] Although FOXP1 is overexpressed in these tumors, its exact significance in their biology is unknown.

Apart from the translocations described, all believed to be mutually exclusive, ENMZL has also been associated with gains of genetic material, in particular partial trisomies of chromosomes 3 (including regions affecting FOXP1, NFKBIZ [NFκB inhibitor zeta], and BCL6) and 18 (affecting NFATC1 [nuclear factor of activated T cells, cytoplasmic, calcineurin-dependent 1], and BCL2). Gains at 6p25 and losses at 6q (affecting TNFAIP3 [tumor necrosis factor, α-induced protein 3])[74,75] and 1p have also been reported.[76]

Consistent with a postgerminal center B-cell origin, ENMZL have rearranged immunoglobulin genes that display somatic hypermutation of their variable regions.[77] In the case of IPSID, there are deletions of the alpha heavy chain gene in the VH and CH1 regions, which result in the production of an abnormal heavy chain that cannot bind light chains to form a complete immunoglobulin molecule.[78]

Therapy for Early-Stage (I/II) Disease

Given its rarity, there are no randomized controlled trials defining the optimal treatment for ENMZL. Most recommendations arise from consensus panels based on data from retrospective or uncontrolled prospective trials. The most extensive body of data has been gathered on gastric ENMZL.

Gastric Extranodal Marginal Zone Lymphoma

This form of ENMZL has a strong association with active *H. pylori* infection. If histologic analysis of the gastric biopsies obtained during staging endoscopy fails to demonstrate *H. pylori*, noninvasive methods, such as breath tests, stool antigen test, or serology, should be used to exclude the infection. Although not necessarily a marker of active infection, the presence of antibodies against *H. pylori* in an individual not previously treated for this bacterium implicates it in the pathogenesis of the lymphoma.

The focus of therapy for *H. pylori*–positive disease is on eradication of the infection with one of the currently recommended regimens for this purpose. These commonly combine a PPI and clarithromycin with a second antibiotic, usually amoxicillin or metronidazole (triple therapy), but this is an issue in flux as resistance to clarithromycin is increasing in several regions.[79] Alternatively, quadruple therapy with a PPI, bismuth, tetracycline, and metronidazole can be used. Most authors recommend 10 to 14 days of treatment because of data suggesting better results than with 7-day courses. According to some authorities, eradication of *H. pylori* should be confirmed with an appropriate test, such as the urea breath test, at least 4 weeks after finishing antibiotherapy and 2 weeks after discontinuing PPI.[79] Pooled data from several prospective and retrospective studies suggest more than 90% eradication rates after initial antibiotherapy.[80] Persistent infection should be treated with a different course of antibiotics, preferably guided by sensitivity tests, because the same data suggests an eradication rate close to 100% after second- or third-line treatments. Repeat endoscopy with biopsies should be obtained 3 months after completion of antibacterial therapy in order to assess tumor response and also to allow histologic confirmation of *H. pylori* eradication. If *H. pylori* is still detected, a different antibiotic combination should be tried and the patient reassessed as above.[9,11]

Responses to therapy are classified according to biopsy findings on endoscopy. Complete histologic response (complete remission [CR]) should be confirmed by a second endoscopy 3 months later and is managed by observation and regular follow-up thereafter as clinically indicated. The presence of small residual lymphoid aggregates early after *H. pylori* eradication, corresponding to a category of *probable minimal residual disease* in the French Study Group of Adult Lymphomas (GELA) grading system for posttreatment evaluation, should also be managed as CR.[81] In some cases, these lymphoid aggregates have been shown to harbor cells with the same monoclonal rearrangements of the original tumor.[82] Nevertheless, these patients do not seem to have an increased risk for relapse and most will have evidence of complete response in a subsequent evaluation.[83]

Patients with overt residual (partial remission [PR]) or stable disease, as long as asymptomatic, can also be managed conservatively, with observation or antibiotherapy as appropriate, for several months. Of interest, responses may occur as late as more than 18 months after completion of antibiotic therapy.[41,83] Progressive or symptomatic disease should be managed with local therapy, with radiotherapy being preferred. Despite its established efficacy in disease control, gastrectomy, because of its immediate morbidity and long-term metabolic complications, is currently reserved for management of rare complications such as perforation or bleeding that cannot be controlled endoscopically.[9,11]

A recent metaanalysis of 1436 patients with early stage (IE-IIE1) *H. pylori*–positive disease on prospective or retrospective studies estimates an overall CR rate of 78% after eradication of *H. pylori*,[84] but with individual study remission rates anywhere from 47 to 100%.[15,17,39-41,82,85-109] On univariate analysis of available data from the same studies, adverse risk factors for achieving remission included the presence of t(11;18), stage greater than IE1, proximal (body or fundus) location of lesions, and Western (versus Asian) residence. No good evidence is available to support adjuvant chemotherapy after anti–*H. pylori* treatment as a means to prevent recurrence in localized gastric MALT lymphomas, although this has only been formally addressed with an additional single agent (chlorambucil).[110]

The management of early-stage *H. pylori*–negative disease is controversial, with some groups suggesting involved field radiation therapy or, if radiation therapy is contraindicated, systemic therapy with rituximab as initial treatment,[9] whereas others propose a trial of anti-*Helicobacter* therapy.[11] The rationale for the latter derives from anecdotal reports of CR in *H. pylori*–negative gastric ENMZL patients that were treated exclusively with antibacterials,[111] with a metaanalysis suggesting a response rate of up to 19%.[112] These patients are assumed to have been infected with *H. pylori* that was missed by diagnostic tests or with a different species of *Helicobacter*, several of which have been recently recognized.[113,114]

Responses to radiation therapy are excellent, with some series reporting CR rates of up to 100% with total doses as low as 30 Gy.[115,116] Recurrence rate is very low in these patients, but follow-up is limited for most series reported.

The optimal follow-up schedule is unknown, although most recommend periodic endoscopies every 3-6 months for the first 5 years and yearly thereafter.[9,11] Long-term follow-up data in patients with complete remission after *H. pylori* eradication document a 7.2% relapse rate overall (2.2% per year).[84] Some of these relapses were associated with *H. pylori* recurrence, and responses to retreatment for *H. pylori* were seen. Whether most complete remissions equate to cures is a question that will require longer follow-up studies. An additional argument in favor of periodic endoscopies is that *H. pylori* may be associated with an increased risk for gastric adenocarcinoma.[117]

Molecular studies should not be done routinely in follow-up biopsy samples, outside of a research protocol. Several studies have shown that molecular disease, defined by the presence of residual t(11;18) or monoclonal immunoglobulin as evidenced by PCR methods, may still be detected even with complete pathologic remissions.[93,118,119] However, this finding is not associated with an increased relapse rate and thus is not helpful for clinical management.

Ocular Extranodal Marginal Zone Lymphoma

The most frequently used treatment modality for all localized forms of ocular adnexal ENMZL is radiation therapy, with treatment specifics dependent on the exact location of the tumor in the orbit. Reported responses are very good, with CR rates of 83% to 100%.[120-128] Local recurrence rates vary between 0% and 17%, and distant recurrences can occur up to 25% over 10 years, although disease-specific survival approaches 100% in most series. The exact site of presentation correlates with the risk for systemic recurrence, the lowest being for conjunctival and the highest for eyelid primaries.[29] Long-term complications, such as cataract formation and xerophthalmia, occur in approximately half the patients.[129]

Based on the success of antibiotherapy for *H. pylori*–associated ENMZL and reports of the presence of *Chlamydophila psittaci* (by PCR, immunofluorescence, or electron microscopy) in ocular tissues of patients affected by ocular adnexal ENMZL, some authors have evaluated a course of an antichlamydial antibiotic in the management of these patients.[43-52] A few studies have reported PR or CR in a significant fraction of these patients. However, the recommendation to treat with a tetracycline at initial diagnosis is still controversial because the reported rates of association with *C. psittaci* are highly variable—some studies suggest prevalences as high as 80%, whereas others are not able to detect the organism in any of the patients. Additionally, a metaanalysis has suggested that the benefit of antibiotherapy may be restricted to specific geographic areas and, even then, is likely to be limited.[130]

Cutaneous Extranodal Marginal Zone Lymphoma

Results for both surgical excision and radiation therapy for limited disease are comparable, with CR rates approaching 100%. Both approaches have a relapse rate (usually limited to the skin) of around 45%. Encouraging results have also been obtained with intralesional injection of rituximab or α-interferon.[36]

Studies from Europe have suggested an association between *Borrelia burgdoferi* infection and ENMZL of the skin, although this has not been reproduced in Asian and American studies.[53-56] In view of this, similar to ocular lymphoma, it has been suggested that a course of a tetracycline may be a reasonable first approach, especially in locations where the association has been documented or when infection by *B. burgdoferi* is detected.

IPSID

Antibiotherapy (varying from single-agent tetracycline to triple-antibiotic therapy with ampicillin, metronidazole, and tetracycline, or an *H. pylori* regimen)[131-134] has long been recognized as being able to induce CR in early-stage disease. Recently, IPSID has been associated with chronic infection with *Campylobacter jejuni*.[42] Therefore treatment of early disease is directed at bacterial eradication. Historic rates of remission vary between 30% and 70%, depending on the study. Maximal responses may take more than 5 months of therapy, and relapses occur in a fraction of patients.

Other Extranodal Marginal Zone Lymphoma

Early-stage ENMZL in other primary sites is managed in a similar way to ocular adnexal or cutaneous forms. When feasible, surgery can be potentially curative and often may be done with primary diagnostic intent. If full resection is achieved, these patients may be observed. Otherwise, for sites not amenable to surgery or if there is residual disease after surgical excision (i.e., positive margins), radiation therapy is the usual preferred approach. If radiation is contraindicated and the patient is asymptomatic, observation is an option. Otherwise, systemic therapy as for advanced stage, preferably one with minimal toxicity, is appropriate.[9,135]

Therapy for Advanced-Stage (III/IV) Disease

The data regarding management of advanced-stage disease are also limited, because most large treatment series with long-term follow-up aggregate all indolent lymphomas and include only a small fraction of patients with MZL among other more frequent histologies. Thus most treatment approaches have been modeled after those for FL (see Chapter 79), and indeed the most common recommendation is that advanced ENMZL be managed as advanced FL.[9] In any case, there is some suggestion that responses may be better, possibly because of a usually lower burden of disease. Eligible patients should be included whenever possible in clinical trials.

As in other indolent lymphomas, extensive disease is likely incurable with current approaches, which together with a generally slow pace of progression means that systemic treatment is not always indicated. Since no benefit in survival has been demonstrated with early systemic treatment of asymptomatic disease, unless a treatable etiology has been identified, initial management of asymptomatic patients with expectant observation is acceptable. While on this watch-and-wait approach, patients should be reassessed approximately every 3 months with history, physical examination, complete blood counts, basic chemistry, and LDH. Any new symptoms or findings suggestive of transformation should be investigated with a repeat biopsy to rule it out. Routine repeat imaging studies are controversial but often used.

Indications for initiating systemic treatment include symptomatic disease due to mass effect or effusion, risk for local compressive disease, bulky lymphadenopathy, symptomatic splenomegaly, B symptoms, cytopenias due to bone marrow involvement, or rapid disease progression. Although unlikely to contribute to regression of established advanced disease, treatment of an underlying infection associated with the lymphoma (such as *H. pylori* for primary gastric ENMZL and *C. jejuni* for IPSID) is advisable in order to remove any inciting factor. Otherwise, as already mentioned, the same treatment approaches used for FL (see Chapter 79) are usually followed for ENMZL. Nonetheless, a few studies specifically addressing MZL are worth reviewing here.

Rituximab

Given its low toxicity, single-agent immunotherapy with rituximab has generated a lot of interest in the management of advanced disease. Two series of approximately 30 patients each, pooling early- and advanced-stage ENMZL, have reported overall response rates of around 75%,[136,137] with up to 48% CR in patients without previous therapy. In one of the series, median time to treatment failure was

22 versus 12 months in chemotherapy-naive versus non-naive patients, respectively.[136] Rituximab has activity in t(11;18)–positive disease.[137]

Alkylating Agents

Single-agent alkylators have also been used in this setting. A study of 24 patients with gastric ENMZL (stages IE or IV) treated with daily oral chlorambucil or cyclophosphamide for 12 to 24 months showed a CR rate of 75%, with the remaining patients achieving PR.[138] Remissions were durable in approximately half of the patients after a median follow-up time of 45 months. Another study of 21 patients (stages I to IV) treated with continuous alkylating drugs documented a CR rate of 42% and 89% in t(11;18)–positive and t(11;18)–negative disease, respectively.[139] After a median follow-up of 7.5 years, CR was sustained in all patients with translocation-negative disease, but in only one patient otherwise.

The combination of rituximab and chlorambucil has produced an impressive 100% CR rate in 13 patients with t(11;18)–positive gastric ENMZL (stages I to IV).[140] No relapses were observed after a median follow-up of 24 months, but long-term data are not available.

Purine Analogues

The purine analogue cladribine has also been used as single-agent therapy in a series of 25 patients (stages I to IV), and CR was obtained in 84% of them. After a median follow-up time of 80 months, seven patients experienced disease relapse.[141] Of note, one of the patients treated developed a myelodysplastic syndrome immediately after the third infusion of the drug.[142] Another purine analogue, fludarabine, has been used in combination with rituximab to treat a series of 22 patients (stages I to IV).[143] At the end of treatment (three cycles, with some patients requiring six), 90% of patients achieved a CR. The progression-free survival rate at 2 years in patients with gastric and extragastric ENMZL was 100% and 89%, respectively. Both purine analogues seem to have activity in t(11;18)–positive gastric ENMZL.

Other Single Agents

Other single chemotherapeutic agents whose use has been reported in ENMZL include oxaliplatin, bendamustine, bortezomib, and vorinostat. In a study of 16 patients (stages I to IV) treated with oxaliplatin, a CR rate of 56% with a median time to response of 4 months was observed.[144] Responses to bendamustine have been documented in patients with relapsed/refractory indolent lymphomas, a small fraction of which were ENMZL: in one series, three cases with CR and three PRs were seen in seven ENMZL patients[145]; in another, four CRs and one PR were observed in six patients.[146] Other studies of patients with relapsed, multiply treated indolent lymphomas report encouraging responses to bortezomib (two cases with PR out of two patients)[147] and vorinostat (one CR and one PR out of nine patients).[148] Long-term follow-up is not available; therefore, the role of these agents as first-line therapy has not been established.

Combination Chemotherapy

Combination chemotherapy regimens reported in ENMZL patients include CVP (cyclophosphamide, vincristine, and prednisone) followed by radiation therapy,[149] FM (fludarabine and mitoxantrone),[150] CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone) followed by CVP,[151] MCP (mitoxantrone, chlorambucil, and prednisone),[152] R-CHOP (rituximab, cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone) and R-CNOP (rituximab, cyclophosphamide, mitoxantrone [Novantrone], vincristine [Oncovin], and prednisone).[153] These regimens have mostly been used in patients who were believed to have more aggressive disease. CR rates vary from 61% to 100%, with relapse rates reaching up to 36% on long-term follow-up. Advanced/transformed IPSID has usually been treated with combination chemotherapy, such as CHOP.[7,154]

Radioimmunotherapy

Radioisotope-conjugated forms of anti-CD20 antibodies (ibritumomab and tositumomab) have also been used both as first-line[155] therapy (eight CRs and one PR in nine patients with ocular adnexal ENMZL) and for relapsed disease[156,157] (three CRs and three PRs in six patients with ocular adnexal ENMZL; four CRs and one PR in six patients with a variety of primary sites). The combination of conventional radiation therapy and rituximab is currently being studied for early-stage follicular lymphoma.[158] There are no published studies of its use on ENMZL.

Therapy for Relapsed Disease

Limited relapses can be retreated, if feasible, with local therapy. Otherwise, treatment considerations are similar to those described for advanced disease. Symptomatic, relapsed extensive disease will usually require an alternative regimen to those previously used.

The role of hematopoietic stem cell transplantation is controversial because most series do not directly address ENMZL and thus most recommendations are again extrapolated from studies of FL.[159-163] Given that most young patients with relapsed systemic ENMZL are likely to succumb to complications of their disease, considering them for allogeneic stem cell transplantation is reasonable, although this should preferably take place on a clinical trial. Encouraging results have also recently been reported with high-dose therapy and autologous stem cell transplantation specifically for MZL.[164]

Prognosis

Overall, prognosis of limited stage ENMZL is excellent, as mentioned in each of the treatment subsections. Even for advanced disease, the expected overall survival at 5 years is greater than 90%, with some series showing survivals similar to those of early disease. As in other indolent lymphomas, transformation to aggressive forms (DLBCL) can occur, but this is thought to be a rare event (less than 10% of cases) associated with acquisition of additional genetic abnormalities.[33] Regardless, even patients in CR after first-line therapy can develop DLBCL. For instance, 0.05% of individuals with gastric ENMZL who underwent successful antibiotic treatment had evidence of DLBCL between 6 months to 2 years after achieving remission.[84] On the other hand, untreated IPSID tends to evolve to large-cell transformation.[7,154]

As for other lymphomas, the International Prognostic Index (IPI)[165] (see Chapter 81) predicts outcomes, with reported 5-year overall survivals of >90%, 70% to 80%, and 40% to 50% for patients with low, low-intermediate/high-intermediate, and high-risk scores, respectively.[28] Nonetheless, the utility of the IPI in ENMZL has been disputed.[166] One of the main criticisms to its use in patients with indolent lymphomas is that prognostic subgroups do not have a good discriminating power, because most patients are assigned to the favorable outcome groups and only very few patients are allocated to the adverse prognostic groups.[167] To circumvent this issue, modifications of the original IPI have been proposed in some cases,[168] but none has been universally adopted.

The recent explosion of genomic analysis of these neoplasms has also led to a plethora of findings that have been shown to have prognostic significance in ENMZL. For instance, the expression of FOXP1 in tumors predicts poor prognosis and transformation to diffuse large B-cell lymphoma.[169] Although these findings are not yet

incorporated into clinical practice, as they become more widely available, they may be useful for risk stratification and therapeutic decisions (see box on Suggested Treatment Approach to Extranodal Marginal Zone Lymphoma).

SPLENIC MARGINAL ZONE LYMPHOMA

Epidemiology and Manifestations

SMZL (Fig. 78-3) is a rare disease, corresponding to <1% of all non-Hodgkin lymphomas.[8] The median age at diagnosis is around 65, but as with ENMZL, the age range is wide and there may be a slight female predominance. The vast majority of patients present with advanced-stage disease involving the spleen (with splenomegaly in more than 80% of patients), abdominal (mainly splenic hilar) lymph nodes, and in 83% to 94% of patients, the bone marrow.[170-173] Peripheral lymphadenopathy is, however, uncommon. Liver involvement is seen in up to one-fourth of patients, and rarely other nonhematopoietic sites can also be involved. B symptoms occur in approximately 25% to 60% of patients, depending on the series.[171,172]

Circulating villous lymphocytes (with short polar villi) can be seen in approximately two-thirds of patients (see Fig. 78-3, *B*) and frank lymphocytosis in up to one-half. This has led to a prior designation of *splenic lymphoma with villous lymphocytes* being given to a specific presentation of this disorder and explains why the disease was called *SMZL with or without villous lymphocytes* in a previous version of the WHO classification. Anemia is seen in about one-half to two-thirds and thrombocytopenia in one-fifth of cases, which can be the result of bone marrow involvement or an autoimmune process (seen in approximately 15% of patients). Between 25% and 40% of patients have a low-level circulating monoclonal immunoglobulin (mostly IgM),[172] and in a few patients, especially in those with active hepatitis C virus (HCV) infection, mixed cryoglobulins can be demonstrated, which can be associated with vasculitis.[174,175]

Pathobiology and Differential Diagnosis

Etiology

Approximately 10% to 20% of SMZL patients from European series have evidence of HCV infection,[170,173] and a significant fraction of these patients can achieve CR after successful treatment of the infection.[174,176] This raises the possibility that, like ENMZL, this disease is associated with chronic antigenic stimulation. However, no other infections have been described in clear connection to SMZL, despite a suggested association with *Plasmodium,*[177] and thus the etiology of most cases is unknown.

Histology

The classic histology of SMZL includes a population of small lymphocytes that surrounds or replaces the germinal centers of the lymphoid follicles of the white pulp, effacing their mantle zone, and progressively merging peripherally with larger, marginal zone–like cells.[178] These cells expand to the interfollicular zones and invariably invade the red pulp (see Fig. 78-3, *A*). A few scattered lymphoblasts are usually present, and as in ENMZL, plasmacytic differentiation can occur. Bone marrow involvement usually gives rise to nodular interstitial lymphoid infiltrates that resemble the histology of the spleen, although the cell types are usually admixed, without distinct zones. Peripheral blood involvement is typically associated with lymphocytes that have short polar villi (Fig. 78-3, *B*), as mentioned above, although the villi may be absent.

Suggested Treatment Approach to Extranodal Marginal Zone Lymphoma

Stage I/II

Gastric* H. pylori*–positive

- Antibiotic therapy
- Repeat endoscopy in 3-6 months
- If still *H. Pylori*–positive and no progression, alternative antibiotic therapy
- Repeat endoscopy in 3 months

Nongastric, gastric* H. pylori*–negative or not responding to antibiotic therapy

- Antibiotic trial for stage I gastric, ocular, or cutaneous?
- Involved field radiation therapy (30 Gy)

Stage III/IV or Relapsed after Antibiotic and Radiation Therapy

- Expectant observation until indication to treat
- Rituximab ± single-agent alkylator/purine analogue or combination chemotherapy (CVP/FND)

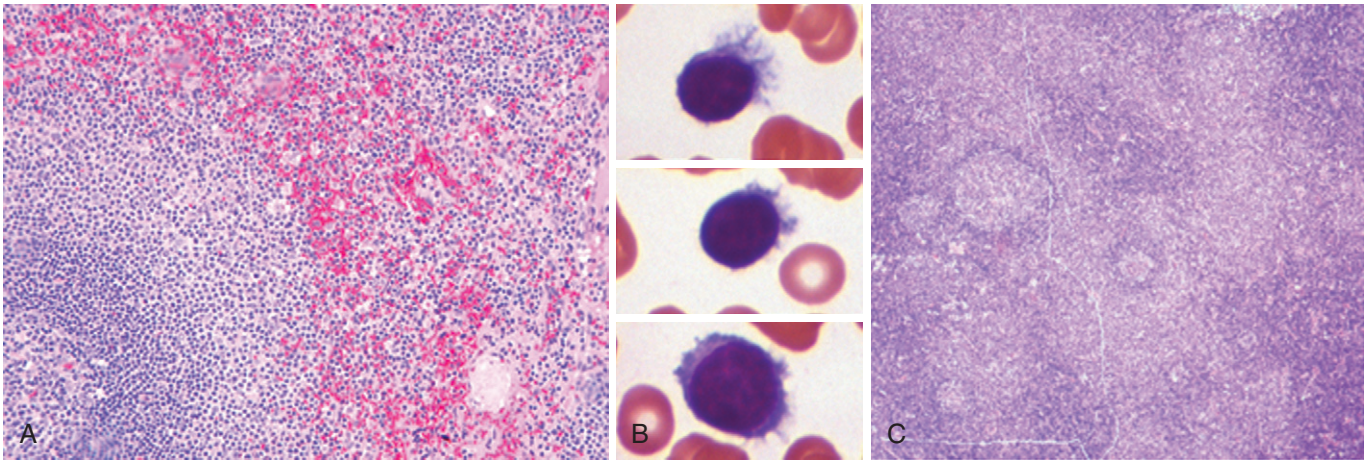

Figure 78-3 SPELINC MARGINAL ZONE LYMPHOMA, VILLOUS LYMPHOCYTES, AND PRIMARY NODAL MARGINAL ZONE LYMPHOMA. **A,** Splenic marginal zone lymphoma is characterized by an expansion of the marginal zone cells *(left)* and their spilling into the red pulp *(right)*. **B,** These cells can also become leukemic and can be recognized on the peripheral blood smear. Note the polar distribution of the cytoplasmic projections. **C,** Primary nodal marginal zone lymphoma is rare, and involvement of a node by extranodal disease must always be ruled out. NMZL is histologically characterized by an expansion of marginal zone cells (formerly referred to as monocytoid B cells) in between reactive germinal centers.

Immunophenotype

The phenotype of SMZL is similar to that of ENMZL (see earlier), but in contrast to the latter, SMZL is usually IgD-positive. The same differential diagnosis considerations apply; additionally, because this disease behaves as a chronic B-cell leukemia, it is of interest that SMZL is negative for annexin A1 and CD25 and usually negative for CD103 (in contrast to hairy cell leukemia).[178] Rare cases may be CD5-positive.[179]

Genetics

A substantial amount of genetic data on SMZL has been accumulated during the last decade. A recent review of 330 patients with SMZL documented del(7q) (affecting different loci in regions q21 to q36) as the most frequent cytogenetic abnormality (≈40% of patients).[173] Gains of genetic material from chromosomes 3 (≈25%), 8 (≈10%), and 12 (≈8%) were also seen frequently. Translocations involving 14q32, different from those seen in ENMZL, occurred in 12% of patients. The translocation t(11;18) was not seen in SMZL. More than 50% of cases had three or more cytogenetic aberrations. Deletions of 8p and 17p (TP53) have been seen in approximately 15% of cases analyzed with DNA microarrays.[76] The biologic significance of these chromosomal abnormalities is unclear at this point, although there are ongoing efforts at clarifying it.[180]

Approximately 50% to 60% of SMZL have evidence of somatic hypermutation of the immunoglobulin genes,[173,180-182] and there is some evidence that, similar to CLL, these cases may have better overall prognosis.[181] Both mutated and unmutated tumors display bias in variable region usage, with predominance of VH1-2 family genes. Intraclonal variation has also been described, which suggests the presence of ongoing mutational events in these lymphomas.[183]

Therapy

Since SMZL behaves indolently, in asymptomatic patients without significant or progressive cytopenias, expectant observation is a reasonable approach. The 5-year overall survival rate of 32 patients with asymptomatic SMZL who never received treatment was 86% in one published series.[184] In another series, 10 out of 14 untreated patients were alive between 1 and 6 years after diagnosis.[185]

Indications for lymphoma treatment are similar to those for advanced-stage ENMZL, including symptomatic splenomegaly. As for other forms of MZL, there are no data from randomized trials guiding selection of therapy, and most recommendations come from consensus opinions of experts in the field.[9]

Anti-HCV Therapy

In patients with evidence of active HCV infection, interferon-α (IFNα) with or without ribavirin (or possibly other active anti-HCV therapy) is recommended. A study of the effects of IFNα in SMZL showed eight complete and one partial hematologic responses in nine HCV-positive patients after clearance of HCV (with two of them requiring addition of ribavirin), versus no responses in six HCV-negative individuals.[176] One patient in CR treated initially only with IFNα had a relapse of the lymphoma with detectable levels of HCV RNA; treatment with interferon-α and ribavirin resulted in second complete virologic and hematologic responses. Of note, evidence of monoclonal immunoglobulin gene rearrangement may persist after successful treatment of HCV and SMZL.[174]

Splenectomy

In general, in symptomatic HCV-negative patients or in those whose disease does not respond to anti-HCV treatment, the most frequently used first-line therapy is splenectomy. A benefit of this procedure, which may often be done for diagnostic purposes in patients with localized disease, is the usual improvement of cytopenias occurring as a result of hypersplenism. Precise response rates to splenectomy are difficult to ascertain. All of 25 patients in a series treated with splenectomy alone had responses, including 2 CRs.[10] Most responses were durable: only 8 of these 25 patients experienced disease progression on long-term follow-up, with a median time to progression of 32 months (with a range of 4 to 137 months).[186] Moreover, all of 16 patients treated with first-line splenectomy in an earlier series had good responses, most likely partial (complete responses could not be assessed because of a lack of bone marrow assessment after treatment); 2 patients progressed subsequently.[185] Finally, another series of 28 patients documented a 5-year overall survival of 71% after splenectomy; no CRs were reported.[184]

Rituximab

For patients who progress after splenectomy or who have contraindications to surgery and require treatment, systemic therapy is appropriate. Rituximab has been used as single agent or in combination with chemotherapeutic drugs. The response rate to single-agent rituximab in a retrospective subseries of 25 patients with splenic and nonsplenic MZL was 88%, which compared favorably with that of 11 patients who received chemotherapy alone (55%).[187] In another retrospective study, rituximab was found to be an effective therapy in 10 of 11 patients with SMZL, with reduction in splenomegaly and improvement in blood counts.[188]

Chemotherapy

Single alkylating agents (chlorambucil or cyclophosphamide) have also been used for treatment of SMZL. Most series are very small, but all report a significant fraction of responses, albeit mostly partial. Fludarabine has produced encouraging results also,[189,190] but the efficacy of cladribine is controversial.[191,192] The use of combination chemotherapy (including CVP and CHOP) has also been reported, but differences between CHOP (or CHOP-like) therapy and other less-intensive regimens could not be demonstrated.[172] In a subseries of 19 patients treated with chemotherapy alone, the 5-year overall survival rate was 64%.[184]

Radiation Therapy

In patients ineligible for any of the aforementioned therapies, radiation therapy to the spleen can be used for symptomatic control. Even low-dose radiation (around 4 Gy) can result in resolution of splenomegaly and correction of cytopenias,[193] at least temporarily.

Although it is tempting to compare the results of observation, splenectomy and systemic therapy, this is not prudent. All published series have considerable selection bias, because patients who are believed to have more aggressive disease have been usually offered more-intensive therapies.

Prognosis

Reported 5-year overall survival rates vary from 65% to 78%,[172,184] with a median survival of 10.4 years.[10] The Italian Lymphoma Intergroup (ILI) has proposed a prognostic model using hemoglobin less than 12 g/dL, LDH higher than normal, and albumin less than 3.5 g/dL as risk factors.[170] Low-risk (no factors), intermediate-risk (1 factor), and high-risk (2 or more factors) patients have 5-year overall survivals of 83%, 72%, and 56%, respectively. Shorter survival has been associated with CD38 expression, unmutated variable region immunoglobulin genes, and expression of a specific set of NF-κB pathway genes (by gene expression array).[180] The presence of both

Suggested Treatment Approach to Splenic Marginal Zone Lymphoma

HCV-Positive
- Interferon-α and ribavirin (or other anti-HCV therapy)

HCV-Negative (or Not Responding to Anti-HCV Therapy) or Relapsed
- Expectant observation until indication to treat
- Splenectomy
- Rituximab ± single-agent alkylator/purine analogue or combination chemotherapy (CVP/FND)
- If contraindication to splenectomy and systemic therapy, low-dose splenic irradiation

del(8p) and del(17p) involving TP53 is associated with worse prognosis, although isolated deletion 17p is not.[76] Transformation to aggressive lymphoma may occur in around 10% of cases[10] (see box on Suggested Treatment Approach to SMZL).

NODAL MARGINAL ZONE LYMPHOMA

Epidemiology and Manifestations

NMZL represents between 1% and 2% of all non-Hodgkin lymphomas. The diagnosis requires the absence of extranodal or splenic disease, the presence of which makes ENMZL and SMZL more likely. The median age at presentation is around 60, and in most series there is a slight female predominance. Most patients present with asymptomatic lymphadenopathy. The most recent series report the presence of B symptoms in less than 20% of patients.[30,171,194-198] Except in three of the published series,[195-197] the majority of patients present with stage III or IV disease (approximately 70% to 80% of cases), with bone marrow involvement detected in up to two-thirds of cases. Anemia and thrombocytopenia have been described in up to 30% and 10% of cases, respectively. A monoclonal IgM is seen in approximately 10% of patients. A pediatric form, with excellent prognosis, has been recently recognized.[199]

Pathobiology and Differential Diagnosis

Etiology

As with SMZL, some series have reported an association with HCV in up to one-fourth of NMZL cases, but with a strong geographic variation.[194,195,197,198] No other clear association has been described.

Histology and Immunophenotype

The histology and immunophenotype of NMZL resembles that of ENMZL or SMZL (see Fig. 78-3, *C*).[200] The frequent presence of monocytoid B cells explains why this disease has been previously called *monocytoid B-cell lymphoma*[201] and *NMZL with or without monocytoid B cells*. A primary ENMZL should always be ruled out with appropriate studies (such as endoscopy) because 30% to 40% of cases presenting as NMZL may in fact represent nodal dissemination of an ENMZL of MALT type.[202,203]

Genetics

The genetic abnormalities most frequently associated with NMZL are partial trisomies of chromosomes 3 and 18, affecting the same regions as in ENMZL. None of the characteristic translocations of ENMZL are seen in NMZL, however.[76] Furthermore, del(7q) is also not observed. More than 75% of cases have mutated immunoglobulin genes.[195,204] Of interest, different VH immunoglobulin gene segments are predominantly involved in HCV-positive and HCV-negative patients, raising the possibility that distinct antigens drive different underlying chronic immune stimulation processes.[205]

Therapy

Few data are available to guide treatment of NMZL, and most recommendations are extrapolated from the management of FL.[9] As in other indolent lymphomas, expectant observation is appropriate for asymptomatic patients. Radiation therapy may be curative for early disease. Symptomatic advanced disease can be managed with the same general approach described for advanced ENMZL, although there is usually a tendency to use combination chemoimmunotherapy identical to that for FL as first-line treatment because of the generally worse outcomes with NMZL as compared with ENMZL.

Prognosis

Most series report worse prognosis for NMZL when compared with the other forms of MZL.[30] Overall survival rates at 5 years vary from 55% to 70% in most series, except for those containing a greater proportion of early-stage disease, which report 5-year survivals of up to 80%. Five-year progression-free survival is around 30%. Relapse in extranodal sites is rare. As in other lymphomas, the IPI correlates with outcomes, as does the Follicular Lymphoma International Prognostic Index (FLIPI)[206] (see Chapter 79). In a series of 47 patients, those with low-, intermediate-, and poor-risk FLIPI scores had a 5-year overall survival of approximately 90%, 70% and 35%, respectively.[194]

CHAPTER 79

CLINICAL MANIFESTATIONS, STAGING, AND TREATMENT OF FOLLICULAR LYMPHOMA

John G. Gribben

Non-Hodgkin lymphoma (NHL) refers to all malignancies of the lymphoid system with the exception of Hodgkin disease. Development of the lymphoid system is a highly regulated process, characterized by differential expression of a number of cell-surface and intracytoplasmic proteins and antigen receptor gene rearrangements, somatic hypermutation, and class switching. Dysregulation of this orderly process can result in humoral deficiency, autoimmunity, or malignancy. The indolent B-cell lymphomas are mature peripheral B-cell neoplasms, excluding those diseases associated with an aggressive clinical course. Despite differences in cell of origin, molecular biology, clinical presentation, and clinical course, the indolent lymphomas share common features, including frequent localization to the principal lymphoid organs, a propensity for bone marrow infiltration and leukemic presentation, and generally, an indolent clinical course. The classification of NHLs has been a challenge for pathologists, as well as for practicing physicians. A number of classifications have been proposed over the years, leading to considerable confusion and difficulty in comparison of outcomes of clinical trials performed using different pathologic classifications. The World Health Organization (WHO) lymphoma classification lists nearly 100 different types of lymphoid neoplasms.[1] This classification uses all available information—morphology, cytochemistry, immunophenotype, and molecular genetics, as well as clinical features. The WHO classification does not include the terminology *indolent lymphoma*. This is a clinical rather than a pathologic term and applies to those lymphomas that tend to grow and spread slowly and produce few symptoms. Indolent lymphomas represent 35% to 40% of NHLs, and follicular lymphoma (FL) is the most common of the indolent lymphomas.

EPIDEMIOLOGY

It was estimated that in 2011 more than 66,000 cases of NHL would be diagnosed in the United States and that almost 20,000 patients would die of their disease (http://seer.cancer.gov/statfacts/html/nhl.html). NHL is extremely heterogeneous in its molecular pathophysiology, histology, and clinical course, and there are major differences in the incidence of subtypes in different geographic locations and among different racial and ethnic populations. This difference in geographic distribution is particularly striking for FL. In the Western world, FL is the second most common lymphoma, accounting for approximately 20% of all non-Hodgkin lymphomas. For example, the incidence of FL in Europe is approximately 2.18 cases per 100,000 persons per year.[2] Incidence rates of indolent lymphomas by gender are shown in Table 79-1. Although most cases are sporadic studies, there is an increased incidence in family members of affected individuals, with a relative risk of 2.3 for siblings of patients.[3] Differentiation of complex environmental factors from true inherited factors remains difficult. The complexity of the epidemiology of NHL mirrors the complexity of the disease and the complexity of the immune system. Since lymphomas do not constitute a single disease, it should come as no surprise that there is no single etiologic factor. The influence on immune dysregulation of viruses, chemicals, radiation, diet, and aging remains unclear. Immune suppression leads to increased incidence of aggressive lymphomas, but not usually indolent lymphomas. FL typically presents in middle age and in older adults, and the median age at diagnosis is 60 years. There is a slight female preponderance.[2]

PATHOGENESIS

FL (Fig. 79-1) is derived from germinal center B cells and maintains the gene expression profile of this stage of differentiation.[4] FL cells express CD19, CD20, CD22, and surface immunoglobulin, and 60% express CD10. A hallmark of the disease is the chromosomal translocation t(14.18) contributing to overexpression of the anti-apoptotic protein BCL2. Morphologically, the disease is composed of a mixture of centrocytes and centroblasts. The third edition of the WHO classification of pathology recommended the use of grades 1, 2, and 3, applied according to the number of centroblasts (0-5, 6-15, and >15 per high-power field, respectively). Grade 3 was further subdivided into 3A (centrocytes still present) and 3B (sheets of centroblasts)—an increased percentage of centroblasts is predictive of poor outcome. A problem with this classification is that it was poorly reproducible among pathologists. Also problematic is the fact that there were no major biologic or clinical differences between grades 1 and 2, whereas grade 3B FL was biologically distinct from grades 1 through 3A, with features suggesting a close relationship to diffuse large B-cell lymphoma (DLBCL).[5] These considerations led to the recommendation to group together FL grades 1 through 3A as FL and to create a new category called FL3B. However, the gene signature in FL3B is closer to FL than to DLBCL.[6] The final classification combined FL grades 1 and 2 into a single category (FL1-2 of 3) and made the distinction between FL3A and FL3B optional rather than mandatory.[7] The fourth edition of the WHO classification recognizes some distinctive clinical and genetic subtypes of FL, including primary duodenal FL and the pediatric type of FL that lacks t(14:18) and usually presents with localized disease. Several variants of FL that lack t(14;18) have some distinctive features—for instance, predominantly diffuse FL with deletions of 1p36 that presents with localized bulky disease in the inguinal region. The gene expression profiles of FL cases with and without t(14;18) show some differences, with t(14;18)–negative FL resembling activated late-stage germinal center B cells.[8]

Although 85% of patients with FL have t(14;18), the pathogenesis of FL remains poorly understood. Recent studies have demonstrated frequent mutations, particularly inactivating mutations of the MLL2 gene, which occurred in 89% of FL cases examined.[9] The major mutations seen in FL are shown in Table 79-2. A notable feature of these findings is that many of the mutated genes are involved in transcriptional regulation. It is likely that posttranscriptional modification of histones is of key importance in germinal center B cells and that the deregulated histone modification due to these mutations is likely to result in reduced acetylation and enhanced methylation, which will act as as driving event in the development of FL. Attention has also been paid recently to the complex interaction among the malignant B cell, the host,[10] and the tumor microenvironment.[4,11,12]

Table 79-1 Incidence Rates of Indolent Lymphomas (Per 100,000 Population)

Type of Indolent Lymphoma	All	Male	Female
Follicular lymphoma	2.186	2.1	2.6
Small B lymphocytic lymphoma/ chronic lymphocytic leukemia	4.92	5.87	4.01
Lymphoplasmacytic lymphoma	0.83	1.0	0.6
Mantle cell lymphoma	0.45	0.64	0.27
Marginal zone lymphoma	0.42	0.4	0.45

Table 79-2 Mutations in Follicular Lymphoma

Gene Name	Abbreviation	Location	Frequency at Diagnosis
Myeloid/lymphoid or mixed-lineage leukemia 2	MLL2	12q	89%
CREB-binding protein	CREBBP	16p	33%
Tumor necrosis factor receptor superfamily member 14	TNFRSF14	1p	25%
E1A-binding protein p300	EP300	22q	15%
Myocyte enhancer factor 2B	MEF2B	19p	13%
Enhancer of zeste homolog 2	EZH2	7q	11%

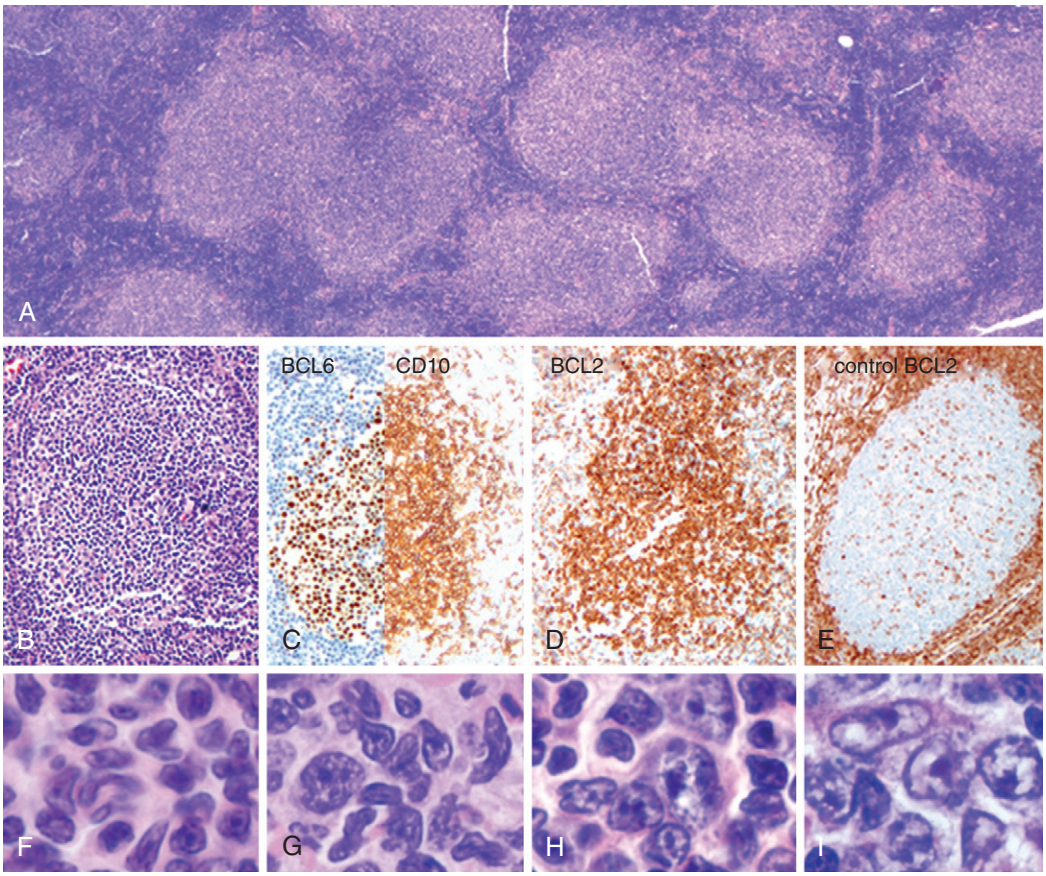

Figure 79-1 FOLLICULAR LYMPHOMA: MORPHOLOGIC AND IMMUNOPHENOTYPIC FINDINGS. **A,** A low-power photomicrograph illustrates a lymph node involved by follicular lymphoma. The lymphoma cells grow in nodules or follicles that resemble the normal lymphoid follicles of a reactive lymph node. However, in the lymphomatous growth, the follicles are crowded, show back-to-back localization, and lack many of the features of their reactive counterparts. At higher power **(B),** the neoplastic follicles lack mantle zones and the normal polarization of small and large germinal center cells (centrocytes and centroblasts, respectively), which occurs due to the cellular response to antigenic stimulation as it sweeps thorough the follicle. The neoplastic follicles stain for the germinal center marker, BCL6 and CD10 **(C);** however, they overexpress BCL2 **(D)** as a result of the associated translocation t(14;18), involving the IgH gene and BCL2. BCL2 is not much expressed in normal germinal center B cells (**E,** control for comparison). Follicular lymphoma is graded by the number of large neoplastic cells (centroblasts) present among the smaller neoplastic cells (centrocytes) (**F** to **I**). The grading system is not entirely accurate, but it provides some framework for subclassifying cases morphologically. Grade 1 is 0 to 5 centroblasts per average 40x field **(F);** between 6 and 15 is grade 2 **(G);** and more than 15 is grade 3A **(H).** Grades 1 and 2 are now considered together. When most of the cells in the neoplastic follicles are centroblasts without centrocytes, the case is considered grade 3B **(I)** (see text for further explanation of grading).

CLINICAL PRESENTATION

The majority of patients with FL present with lymphadenopathy in one or more sites. FL patients often present with a long history of having noticed painless increased lymph nodes over a number of years before presentation. Lymphadenopathy may wax and wane, and spontaneous remissions can occur, albeit rarely.[13] Disease transformation to a more aggressive histologic type is a common terminal event.[14]

Extranodal disease is relatively common and can affect any organ. The most common sites of extranodal disease include the bone marrow, skin, GI tract, and bone. Symptoms may be nonspecific or related to the site of disease involvement. Many patients are asymptomatic, but some, particularly those with bulky disease, may present with B symptoms defined as fever, drenching sweats, or weight loss of more than 10% of body weight. Patients may present with evidence of bowel obstruction from intraabdominal lymphadenopathy and retroperitoneal disease may manifest as obstructive uropathy. Inguinal disease may cause compression of the venous system with deep venous thrombosis. CNS involvement can occur, but this is uncommon in FL.

DIAGNOSIS OF INDOLENT LYMPHOMAS

Suggested guidelines for the diagnosis of indolent lymphomas have been outlined by the National Comprehensive Cancer Network (http://www.nccn.org/) and by the European Society for Medical Oncology.[15] In all cases, possible diagnosis should be confirmed by excisional biopsy of an accessible lymph node (LN) with review by an expert hematopathologist with expertise in lymphoma diagnosis. Fine-needle aspiration is not appropriate for diagnosis in these conditions, and sufficient material must be obtained for immunophenotyping and genetic studies as required for diagnosis and assay for prognostic markers. In patients without easily accessible peripheral nodes, computed tomography (CT) or ultrasound guided biopsy are typically well tolerated. Where possible, consent should be obtained for the procurement and storage of use of excess tissue from LN biopsies at the time of presentation and at each subsequent relapse of disease for research purposes to investigate the molecular biology of these diseases. Bone marrow biopsy provides essential information and should be performed routinely. The yield of bilateral bone marrow biopsy is moderately higher (15%) than that of unilateral biopsy.

Initial investigations are listed in Table 79-3. Physical examination should include careful examination of all peripheral lymph node groups, including the cervical, supraclavicular, axillary, and inguinal chains and examination of Waldeyer ring. Abdominal examination should focus on evaluation of any intraabdominal masses, with particular attention paid to detection of enlargement of the liver or spleen. The skin should be carefully examined. Patients may present with pleural or pericardial effusions, although this is less common than in the aggressive lymphomas.

Laboratory investigations should include a complete blood count to evaluate for cytopenias, which may be evidence of bone marrow infiltration or of autoimmunity. A white blood count with differential and examination of the peripheral blood smear may elucidate leukemic involvement with disease. Baseline electrolytes (including calcium and phosphate), creatinine levels, and liver function tests are important to determine organ dysfunction that may be related to direct infiltration by lymphoma. Elevation of lactate dehydrogenase (LDH) is an important prognostic factor and may be a useful indicator of transformation from indolent to aggressive lymphoma.

Initial staging workup also includes a CT scan of the chest, abdomen, and pelvis. Particular attention should be paid to sites of bulk disease and to the number of involved sites. Liver biopsy may be indicated based on abnormal imaging or laboratory testing.

Table 79-3 Initial Evaluation of Follicular Lymphoma

Physical examination with attention to peripheral nodes, abdomen
Complete blood count; evaluation of peripheral blood
Liver function tests; LDH; beta-2-microglobulin
CT scans of chest, abdomen, pelvis (PET scan if indicated)
Lymph node biopsy with review by an expert lymphoma histopathologist
Bone marrow biopsy/aspirate
Other studies as indicated

STAGING

The staging of NHL uses the Ann Arbor Classification (Table 79-4). CT scans have replaced lymphangiography. The impact of newer technologies such as positron emission tomography (PET), which are included in the revised guidelines for aggressive lymphomas,[16] has been much less studied in the indolent lymphomas. Considerable heterogeneity exists in uptake of fluorine-18 fluorodeoxyglucose based on histology, but PET demonstrates 94% sensitivity and 100% specificity for staging in FL.[17] Although data are still insufficient to recommend PET scans routinely in patients with FL, these scans can be useful to direct biopsy in cases in which transformation is suspected.

NATURAL HISTORY

Until recently, there was little evidence that the natural history of FL had changed over the last 30 years from the median survival of 10 years from diagnosis.[18] The overall probability of survival of FL patients treated at St. Bartholomew's Hospital is presented in Fig. 79-2. Evidence now shows that the introduction of monoclonal antibodies in combination with chemotherapy has finally led to an improvement in survival, with the result that the median survival is now 12 to 14 years.[19,20] The clinical course is extremely variable, with some patients having an extremely aggressive course and death within 1 year, whereas others may live for more than 20 years and never require therapy. Therefore prognostic markers are needed to help identify those patients who will have a good or poor prognosis. The Follicular Lymphoma International Prognostic Index (FLIPI), a five-factor prognostic index based on the clinical characteristics of age, stage, number of nodal sites, hemoglobin level, and LDH level (Table 79-5), defines three prognostic risk groups of almost equal numbers of patients.[21] This tool is useful in assessing the likely need for early treatment of patients and their potential outcome, as well as in comparing the outcomes of different clinical trials. A revised FLIPI2 (incorporating β_2 microglobulin, diameter of largest lymph node, bone marrow involvement, and hemoglobin level) may better discriminate the outcome for patients requiring treatment (Table 79-6).[22]

Table 79-4 Ann Arbor Staging

Stage	Criteria
I	Involvement of 1 lymph node (I) or 1 extralymphatic organ or site (IE)
II	Involvement of 2 or more lymph nodes on same side of diaphragm (II) or localized extralymphatic organ or site and 1 or more involved lymph node on same side of diaphragm (IIE)
III	Involvement of lymph nodes on both sides of diaphragm (III) or same side with localized involvement of extralymphatic site (IIIE), spleen (IIIS), or both (IIIS+E)
IV	Diffuse or disseminated involvement of extralymphatic organ or tissues with or without lymph node enlargement

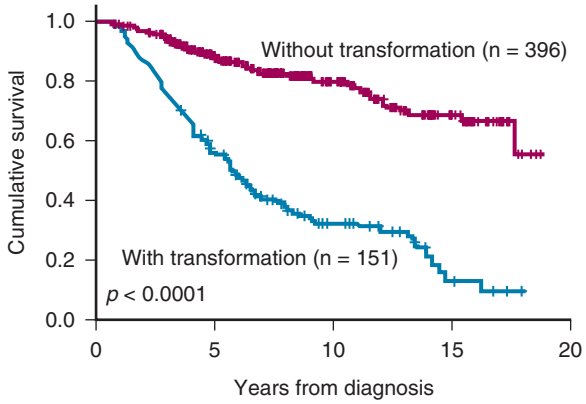

Figure 79-4 OVERALL PROBABILITY OF SURVIVAL OF PATIENTS WITH FOLLICULAR LYMPHOMA WHO HAVE AND HAVE NOT UNDERGONE HISTOLOGIC TRANSFORMATION.

An important factor for the prognosis of FL is histologic transformation of the disease.[14] This factor was evaluated in the database of patients treated for FL at St. Bartholomew's Hospital. Fig. 79-3 shows the actuarial risk for these patients undergoing histologic transformation; the survival of patients with and without transformation is illustrated in Fig. 79-4. Despite a considerable body of information on the pathologic and molecular events associated with HT, the pathogenesis of transformation remains elusive and the molecular events that have been identified have not been translated into changes in clinical practice. A major focus of research is the attempt to identify patients at high risk for transformation early in their clinical course, but this is not yet possible. The outcome of patients who undergo transformation after already having received multiple lines of therapy remains poor, but for those patients who undergo transformation and then receive their first therapy for the transformed disease, the use of chemoimmunotherapy has led to a significant improvement in prognosis.

TREATMENT OF FOLLICULAR LYMPHOMA

For most cases of FL, the goal of therapy has been to maintain the best quality of life and to treat patients only when they develop symptoms. Any alteration to this approach requires demonstration of improved survival with early institution of therapy or identification of criteria that define patients sufficiently "high risk" to merit early

Table 79-7 Treatment Strategies for Indolent Lymphomas

LOCALIZED DISEASE
Radiotherapy
"Watch and wait"
ADVANCED-STAGE DISEASE
"Watchful waiting"
Chemotherapy
Alkylating agents
Bendamustine
Purine analogues

Conjugated—radioimmunoconjugates and immunotoxins
Chemotherapy + monoclonal antibodies (chemoimmunotherapy)
High-dose chemotherapy plus autologous/allogeneic stem cell transplantation
Reduced-intensity conditioning allogeneic transplantation
Palliative radiotherapy

Management of Follicular Lymphoma

Patients most often present with asymptomatic lymphadenopathy. The diagnosis should be made by excisional biopsy and review by an expert hematopathologist. In the absence of symptoms requiring treatment, an expectant "watch and wait" approach is the treatment of choice. While in this phase of treatment, patients should be followed every 3 to 6 months for history, physical examination, and laboratory results with radiologic restaging as clinically indicated. Once a decision to treat has been made, no clear treatment algorithm exists, and a number of treatment options are available. The treatment goal, whether palliative or potentially with curative intent, is dependent on the age and performance status of patients. Enrollment in a clinical trial should be the treatment of choice. For younger patients in whom high-dose therapy may be indicated later in their disease course, it is best to avoid profoundly myelotoxic regimens. The role of maintenance therapy in first remission using interferon-α remains controversial, and the use of rituximab maintenance therapy in first remission remains the focus of ongoing clinical trials. The choice of therapy after first relapse depends again on the goal of therapy; however, it is also dependent on the previous therapy, response, and duration of response. Autologous or allogeneic stem cell transplantation has a role to play in selected younger patients with this disease.

therapy. There are many available therapies but no consensus on an optimal first-line or relapse treatment. Despite the lack of data demonstrating any benefit for early therapy, patients are being treated earlier in their disease course. There is no clear-cut treatment pathway for patients with FL, and although we have a good evidence base to decide on a particular treatment, little or no data exist regarding the optimal sequencing of treatment approaches in this disease. In the absence of such data, treatment choices remain empiric and should always involve discussion regarding patient choice and the goal of therapy. These choices will likely become even more complicated by the many new treatment agents currently being investigated in preclinical and clinical studies—in particular, the novel monoclonal antibodies and agents that alter the antiapoptotic pathways and B-cell receptor signaling pathways. The impact of these new agents on practice will depend on the results of ongoing clinical trials.

Multiple treatment approaches exist for advanced stage low-grade lymphomas, and these patients are best treated in the setting of clinical trials. Options range from a watch-and-wait expectant management approach, to single-agent chemotherapy or monoclonal antibody therapy with rituximab, to combination chemoimmunotherapy with use of autologous or allogeneic stem cell transplantation (SCT) (Table 79-7). Patients remaining on an expectant course should be followed every 3 months with history, physical examination, and blood counts including LDH. Special attention should be paid to any change in symptoms that might be suggestive of transformation, which is an indication for repeat biopsy to examine for histologic evidence to confirm transformation. Repeat scanning is not routinely performed unless indicated by symptoms or signs.

Since there is no clearly defined treatment algorithm for most patients with indolent lymphomas, eligible patients should be included in clinical trials whenever possible. This ensures delivery of optimal care for patients and helps inform the design of subsequent trials, hopefully leading to cure. Information on available clinical trials can be found at the Clinical Trials registry and database (www.clinicaltrials.gov) (see box on Management of Follicular Lymphoma).

WHEN TO INSTITUTE THERAPY

Stage I-II (Limited Stage Disease)

Radiation therapy is the preferred treatment for the approximately 10% of patients who present with limited stage, nonbulky disease. This treatment option is offered with curative potential[23] but must be weighed against the potential toxicity of the radiation therapy to other tissues. In patients with large tumor burden or other adverse risk factors, systemic therapy is indicated. There is no proven role of radiation consolidation therapy.

Expectant management is the treatment of choice for asymptomatic patients with low-bulk disease until clear indications for initiation of treatment are seen, except for those patients enrolled in a clinical trial assessing the impact of early therapy. This approach is based on the demonstration of no survival advantage for institution of immediate treatment compared with deferred treatment until time of progression.[24] Three randomized trials, performed in the pre-rituximab era, confirmed no survival benefit for early therapy.[25-27] In a National Cancer Institute (NCI) study of 104 newly diagnosed patients with FL, deferred treatment was compared with immediate treatment with the ProMACE-MOPP regimen (see table 79-10) followed by total nodal irradiation. An updated analysis of these data is long overdue, but no difference in overall survival (OS) was found between the two arms of the study at the time of the last analysis.[25] The Groupe Pour l'Etude de Lymphome Folliculaire (GELF) used defined criteria for patients in whom immediate therapy was not believed to be indicated (Table 79-8) and randomized 193 patients to receive deferred treatment or to receive prednimustine 200 mg/m^2/day for 5 days per month for 18 months or IFN-α 5 MU/day for 3 months followed by 5 MU three times per week for 15 months.[26] The median OS time was not reached and the OS was the same in all three arms of the study. The British National Lymphoma Investigation (BNLI)[27] compared treatment in 309 patients with asymptomatic advanced-stage, indolent lymphoma—158 of these patients were randomized to receive immediate therapy with oral chlorambucil 10 mg per day continuously, and 151 patients were randomized to deferred treatment until disease progression (see Table 79-8). In both arms, local radiotherapy to symptomatic nodes was allowed. At a median follow up in the study of 16 years, no difference was seen in OS or cause-specific survival between the two groups.

A major clinical trial question is whether identification of clinical or molecular risk factors can help determine which patients are candidates for early therapy. A survival predictor score has been developed from gene expression profiling studies.[4] The results from this study suggest that the molecular determinants of biologic heterogeneity are already present in the diagnostic LN biopsies rather than by the later acquisition of secondary genetic changes. A major

Table 79-8 Criteria for Delaying Treatment of Follicular Lymphoma

GELF*

All of the following:

- Maximum diameter of disease <7 cm
- Fewer than 3 nodal sites
- Absence of systemic symptoms
- Spleen <16 cm on CT
- No significant effusions
- No risk for local compressive symptoms
- No circulating lymphoma cells or marrow compromise (Hb < 10 g/dL, WBC < 1.5 or platelets <100,000/dL)

BNLI†

Absence of all of the following:

- B symptoms or pruritus
- Rapid generalized disease progression
- Marrow compromise (Hb ≤ 10 g/dL, WBC < 3.0 or platelets <100,000/dL)
- Life-threatening organ involvement
- Renal infiltration
- Bone lesions

component of the gene expression prognostic signature is related to immune cells in the tumor microenvironment.[11,12,28] Future guidelines for treatment will likely be based on clinical staging systems, genetic profiles, and immune response signatures, but these factors do not yet provide guidance in terms of who should have immediate therapy.

Little evidence is available to suggest that we should change our practice of "watch and wait" for the asymptomatic patient with low-bulk disease; regardless, data demonstrate that this practice is becoming much less common in the United States.[29] The National LymphoCare Study is a prospective observational survey designed to assess presentation, prognosis, treatment, and clinical outcomes in patients newly diagnosed with FL. The treating physician determines management according to clinical judgment with no prescribed treatment regimen; data are then recorded regarding histology, stage, therapy, response, relapse, and death. The first treatments offered are listed in Table 79-9. Among 2708 patients enrolled at 265 centers, only 17.7% of patients were initially observed; of these, 22% received active therapy within 1 year and 31% within 2 years. This observation is in stark contrast to the data from the BLNI study, demonstrating that censored for nonlymphoma death, 19% of patients and 40% for those older than 70 years who were randomized to expectant management still did not require therapy at 10 years.[27]

TREATMENT APPROACHES

Treatment is indicated in patients with symptomatic disease, bulky lymphadenopathy and/or splenomegaly, risk for local compressive disease, marrow compromise, or rapid disease progression. Once indicated, numerous treatment approaches are available (Table 79-10). Newly diagnosed patients (and their physicians) may be quite confused by the choice of vastly different treatment approaches—for instance, a "do nothing" approach versus a treatment associated with considerable morbidity and mortality, such as stem cell transplantation (SCT). Thus considerable consultation time is required to review available treatment approaches. Staging of response in indolent lymphomas is by the revised response criteria.[16] Depending on the treatment approach used, restaging after two to three cycles of therapy can be useful to ensure responsiveness, and the patient is then fully restaged after completion of therapy. Although curative approaches are being sought for aggressive lymphomas, the failure to achieve complete remission or complete eradication of disease does not have the same implication in indolent lymphomas as in aggressive lymphomas, and a PR may be a sufficient response to therapy to alleviate symptoms. The more commonly used regimens in indolent lymphoma cases are shown in Table 79-10.

In the absence of a clear standard of care with curative potential, optimal first-line treatment remains enrollment in randomized clinical trials wherever possible. In the National LymphoCare Study,[30] academic sites are more likely than community sites to treat patients in clinical trials (12% versus 4% of patients), but it is lamentable that only 6% of patients were enrolled in clinical trials. For patients who are not eligible for clinical trials or who refuse entry, data demonstrate higher response rates, longer duration of responses, and perhaps, improved survival with chemoimmunotherapy. Many investigators favor alkylator over fludarabine-based regimens for FL, based on concerns regarding the ability to obtain stem cells for later use for autologous SCT in patients who were treated with fludarabine.[31] It is suggested that more aggressive first-line therapy be offered to patients who progress within 1 year of presentation, because these patients have a worse outcome.[26] Older adult patients or those with poor performance status remain candidates for single-agent chlorambucil. Single-agent monoclonal antibody therapy is appropriate for patients who choose to avoid chemotherapy; this is a reasonable treatment choice based on the results of clinical trials of prolonged or maintenance therapy with rituximab. Although data suggest a survival advantage with the use of interferon (IFN)-α in combination with chemotherapy, this approach is associated with a significant side effect profile and is rarely used in the United States. Optimal results are seen when radioimmunoconjugates are used earlier in the disease course. There is no indication for the use of high-dose therapy and SCT in first remission in FL, unless as part of a clinical trial.

Data from the National LymphoCare Study[29] demonstrate that chemoimmunotherapy is now the treatment of choice of physicians in the United States (see Table 79-9). No randomized trials demonstrate a benefit for the addition of anthracyclines, but the

Table 79-10 Chemotherapy Regimens in Indolent Lymphomas

CVP (EVERY 21 DAYS)

- cyclophosphamide 750 mg/m^2 IV on day 1
- vincristine 1.4 mg/m^2, up to a maximal dose of 2 mg IV, on day 1
- prednisone 40 mg/m^2 daily PO on days 1 to 5

Patients being treated with R-CVP also received 375 mg/m^2 of rituximab IV on day 1 of each therapy cycle.[72]

CHOP (EVERY 21 DAYS)

- cyclophosphamide 750 mg/m^2 IV on day 1
- hydroxydaunomycin 50 mg/m^2 IV on day 1
- vincristine (Oncovin) 1.4 mg/m^2, up to a maximal dose of 2 mg IV, on day 1
- prednisone 100 mg daily orally on days 1 to 5

Patients being treated with R-CHOP also received 375 mg/m^2 of rituximab IV on day 1 of each therapy cycle[73] or by alternate schedule.[70]

CNOP (EVERY 21 DAYS)

- cyclophosphamide 750 mg/m^2 IV on day 1
- mitoxantrone (Novantrone) 10 mg/m^2 IV on day 1
- vincristine (Oncovin) 1.4 mg/m^2, up to a maximal dose of 2 mg IV, on day 1
- prednisone 50 mg/m^2 daily orally on days 1 to 5

CHVP-IFN (EVERY 28 DAYS FOR 6 MONTHS, THEN EVERY 2 MONTHS FOR 6 MONTHS)[88]

- cyclophosphamide 600 mg/m^2
- hydroxydaunomycin 25 mg/m^2
- etoposide (Vepesid) 100 mg/m^2 on day 1 (replaces original teniposide 60 mg/m^2 on day 1)
- prednisolone 40 mg/m^2 on days 1 to 5
- interferon-α-5, 3 times a week

Patients being treated with R-CHVP also received 375 mg/m^2 of rituximab IV on day 1 of each therapy cycle for six cycles.

FMD (EVERY 28 DAYS)

- fludarabine 25 mg/m^2 IV on days 1-3
- mitoxantrone 10 mg/m^2 IV on day 1
- dexamethasone 20 mg /day PO days 1 to 5

Patients being treated with R-FMD also received 375 mg/m^2 of rituximab IV on day 1 of each therapy cycle.

PROMACE-MOPP

Cycles repeated every 28 days

Day 1

- cyclophosphamide 650 mg/m^2 IV
- doxorubicin 25 mg/m^2 IV
- etoposide 120 mg/m^2 IV
- prednisone 60 mg/m^2 orally daily days 1-14

Day 8

- mechlorethamine 6 mg/m^2 IV
- vincristine 1.4 mg/m^2 (maximum 2 mg) IV on day 8
- procarbazine 100 mg/m^2 orally daily days 8-14

Day 15

- methotrexate 500 mg/m^2 IV on day 15
- leucovorin 50 mg/m^2 orally every 6 hours for four doses beginning 24 hours after methotrexate

R-HYPER-CVAD (EVERY 21 DAYS)*

Cycles I, 3, 5, and 7

- rituxumab 375 mg/m^2 IV on day 1
- cyclophosphamide (with mesna) 300 mg/m^2 IV over 3 hours every 12 hours on days 2-4 (total six doses)
- vincristine 1.4 mg/m^2 (maximum 2 mg) IV on days 5 and 12
- doxorubicin (Adriamycin) 16.6 mg/m^2 IV by continuous infusion on days 5-7
- dexamethasone 40 mg/day PO/IV on days 2-5 and days 12-15

Cycles 2,4, 6, and 8

- rituxumab 375 mg/m^2 IV on day 1
- methotrexate 200 mg/m^2 IV over 2 hours, followed by 800 mg/m^2 IV continuous infusion over 22 hours on day 2
- leucovorin 50 mg PO starting 12 hours after completion of methotrexate infusion, followed by 15 mg PO every 6 hours for 8 dosed until the methotrexate level is less than 0.1 μM/L
- cytarabine 3000 mg/m^2 IV over 2 hours every 12 hours on days 3 and 4 (4 doses total)

*From Romaguera JE, Fayad L, Rodriguez MA, et al: High rate of durable remissions after treatment of newly diagnosed aggressive mantle-cell lymphoma with rituximab plus hyper-CVAD alternating with rituximab plus high-dose methotrexate and cytarabine. *J Clin Oncol* 23:7013, 2005.

combination of rituximab, cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), and prednisone (R-CHOP) is heavily favored over rituximab, cyclophosphamide, vincristine, and prednisone (R-CVP) or fludarabine-based regimens. Choice to initiate therapy was associated with FLIPI, stage, and grade; however, FLIPI was not associated with the decision to use any specific treatment approach. Significant regional and center differences were observed, strongly suggesting that physician preference is the predominant factor that drives initial therapy. For example, initial "watch and wait" was used in 31% of cases in the Northeast but only in 13% in the Southeast; fludarabine-based chemoimmunotherapy was used in 18% of patients in Southwest but only in 3% in the Northeast.

Alkylating Agents

The alkylating agents chlorambucil and cyclophosphamide, with or without prednisone and CVP or CHOP, and other alkylator-based combination chemotherapy regimens have been the standard of therapy for FL decades. Single-agent alkylators at different doses and schedules produce overall response (OR) rates of 50% to 75% in FL.[32,33] Comparable response rates, but higher complete remission (CR) rates with longer progression-free survival (PFS), are seen with CVP compared with chlorambucil, but with no survival advantage.[34,35] The addition of anthracyclines has not improved the response rate or duration of the response,[36,37] but its use may be associated with a lower risk for histologic transformation.[25,38] This finding needs to be confirmed, particularly in the era of chemoimmunotherapy.

Bendamustine

Bendamustine is a potent alkylating agent that has been demonstrated to have substantial efficacy in NHL patients, including those with FL. Bendamustine is highly effective in rituximab-refractory FL and in patients whose disease is refractory to other alkylating agents. It has also demonstrated considerable efficacy in previously untreated FL, both alone and in combination with rituximab or other chemotherapeutic agents.[47,48] Increased understanding of the mechanisms of action of bendamustine and its efficacy in combination with rituximab in newly diagnosed or relapsed/refractory FL has led to investigation of other combinations. Ongoing studies are examining bendamustine with bortezomib, lenalidomide, temsirolimus, ofatumumab, GA101, and other novel agents.

Purine Analogues

The purine analogues have been studied extensively in various types of indolent lymphoma. Fludarabine monotherapy produces response rates of 65% to 84%, with 37% to 47% CR in previously untreated FL patients.[39] In a randomized trial of 381 previously untreated patients with indolent lymphoma, CR rates were higher with fludarabine than with CVP.[40] Fludarabine combinations result in increased response rates, with an 89% CR rate in an Eastern Cooperative Oncology Group (ECOG) trial combining fludarabine and cyclophosphamide (FC),[41] whereas fludarabine and mitoxantrone (FM) produced a 91% OR, 43% CR, and 2-year DFS of 63%.[42] A higher CR rare was seen with FM (68%) compared with CHOP (42%) in a randomized trial.[43] The use of alkylator-based regimens or purine analogue–based regimens appears to vary geographically, suggesting personal preference for the use of regimens in which the clinician has experience, rather than alterations of practice based on the results of the published studies. In CLL/SLL, fludarabine is associated with a higher response rate and longer duration of response than chlorambucil,[44] but with no OS advantage. The use of fludarabine in combination with cyclophosphamide is associated with a higher response rate and longer duration of response compared with fludarabine alone in randomized trials.[45] The highest response rates have been with fludarabine, cyclophosphamide, and rituximab (FCR).[46]

Biologic Therapy

Based on improved survival in clinical trials[21,49,50] and metaanalysis of phase III trial data,[51] IFN-α has been approved by the Food and Drug Administration (FDA) for the treatment of advanced-stage FL in combination with anthracycline-based chemotherapy. IFN-α has been widely used in Europe, but not in the United States, where it is believed that its toxicity profile outweighs any potential benefit. In the Southwest Oncology Group (SWOG) study,[52] 571 patients with stage III and IV indolent lymphoma were treated with ProMACE-MOPP, and 279 responding patients were randomized to 24 months of observation versus treatment with IFN-α. No statistically significant difference was seen in PFS or OS between the observation group and the IFN-α group at 4 years.

Monoclonal Antibody Therapy

Monoclonal antibodies are the most exciting agents to emerge in the treatment of indolent lymphomas. The most widely used monoclonal antibody is rituximab, a chimeric unconjugated antibody against the CD20 antigen. Rituximab is licensed by the FDA and the European Agency for the Evaluation of Medicinal Products (EMEA) for (1) the treatment of patients with relapsed or refractory, CD20-positive low-grade FL, (2) the first-line treatment of CD20-positive FL in combination with CVP chemotherapy, and (3) the treatment of CD20-positive low-grade NHL in patients with stable disease or patients who achieve a PR or CR following first-line treatment with CVP chemotherapy. The use of this agent has had a profound effect in improvement in survival in patients with FL.[19,20,53]

Following phase I studies,[54] rituximab at a dose of 375 mg/m^2 weekly for 4 weeks was selected for the pivotal phase II trial,[55] and although this remains the standard dose, the optimal dose and schedule of rituximab are still unknown. In relapsed FL patients, OR to rituximab monotherapy was 60% with a median PFS for responders of 13 months. Factors associated with lower response rates include chemoresistant disease,[55] bulky disease,[56] and treatment late in the disease course.[57] OR was 73% in previously untreated patients with low-bulk disease[58]; some of these patients have needed no further treatment and have no evidence of polymerase chain reaction (PCR)–detectable minimal residual disease (MRD) after 7 years.[59] Extended use with 8 weeks of treatment (instead of 4 weeks) is associated with improvement in OR and duration of response.[60] Comparable or even longer durations of response have been observed with retreatment.[61]

Table 79-11 Studies of Rituximab Maintenance Therapy in Indolent Lymphomas

Trial	Disease Setting	Diseases Included	Previous Therapy
ECOG[62]	First-line	Follicular Small lymphocytic	CVP
SAKK[63]	First-line Relapsed/refractory	Follicular Mantle cell	Rituximab
EORTC[64]	Relapsed/refractory	Follicular	CHOP vs. R-CHOP
GLSG[65]	Relapsed/refractory	Follicular Mantle cell	FCM vs. R-FCM
LYM-5[66]	Relapsed/refractory	Follicular Small lymphocytic	Rituximab

A number of trials in front-line and in relapsed/refractory patients have investigated the potential benefits of extended or maintenance rituximab treatment,[62-68] and all of these trials demonstrated prolonged time to progression in patients receiving maintenance rituximab (Table 79-11). Results from the E1496 randomized trial from ECOG and from the Cancer and Leukemia Group B (CALGB) comparing CVP alone with CVP followed by rituximab in patients with advanced-stage FL demonstrated that addition of rituximab maintenance significantly improved OS[62] and led to FDA approval for rituximab therapy in patients responding to CVP chemotherapy. The results of the PRIMA (primary rituximab and maintenance) study demonstrated an advantage in PFS for maintenance rituximab therapy offered after initial chemoimmunotherapy.[68] It is too soon to determine whether this will have an impact on OS, and questions remain as to whether this should become standard of care.[69]

Chemoimmunotherapy

In a phase II study, 40 patients with indolent lymphoma were treated with six infusions of rituximab (375 mg/m^2 per dose) in combination with six doses of CHOP chemotherapy (R-CHOP)[70]; OR was 95%, with 55% CR. In a phase II study of 40 patients with indolent lymphomas, rituximab in combination with fludarabine produced OR of 90%, with 80% CR, with similar response rates in treatment-naive and previously treated patients.[71]

A number of randomized trials show a benefit for the use of rituximab with chemotherapy compared with chemotherapy alone (Table 79-12).[64,72-75] Each study showed an improvement in time to treatment failure (TTF), and more recent follow-up data suggest improved OS in patients treated with chemoimmunotherapy compared with chemotherapy alone. A metaanalysis of these trials demonstrates that OS, OR, and disease control are significantly better with chemoimmunotherapy compared with chemotherapy for FL and mantle cell lymphoma.[76] Data from the German Low-Grade Study Group (GLSG) suggest that it is the addition of rituximab that has led to the recent improvement in survival of patients with FL.[20] An independently assessed analysis of the clinical benefits provided by rituximab in relation to cost concluded that it is a highly cost-effective treatment.[77]

The largest FL trial ever reported is the PRIMA study.[68] This study enrolled 1217 patients to receive initial chemoimmunotherapy. Treatment was from three possible regimens, but it is important to note that 75% of patients received R-CHOP. All patients had fulfilled the criteria for treatment, and 80% had FLIPI intermediate- or high-risk features. Responding patients were randomized to receive no further therapy or to receive 12 doses (every 8 weeks) for 2 years.

Table 79-12 Randomized Trials of Chemotherapy Versus Chemoimmunotherapy

Study	Treatment, Number of Patients	Median FU (months)	OR (%)	CR (%)	Median TTF (months)	OS (%)
M39021[72]	CVP, 159	53	57	10	15	77

					$p < 0.0001$	$p = 0.029$

CR, Complete remission; *FU*, follow-up; *OR*, overall response.

Patients who received rituximab maintenance therapy had significantly better rates of 3-year PFS than did those who received observation (75% versus 58%), and the benefit to maintenance was observed in all FLIPI groups. Time to next treatment was also longer in the maintenance group than in the observation group. Increased toxicities were seen in the maintenance group, most being infections, but these were largely self-limiting.

Conjugated Radiolabeled Monoclonal Antibody Therapy

Complexing a radioisotope to a monoclonal antibody (radioimmunoconjugate) might be expected to improve efficacy over antibody therapy alone. Tositumomab complexes ^{131}I (radioactive iodine) to the anti-B1 antibody and has been studied extensively in the treatment of heavily pretreated patients[78] and untreated patients,[79] as well as for retreatment of indolent lymphomas.[80] Best responses are seen in previously untreated FL patients—95% OR, 75% CR, and 80% of assessable patients achieving eradication of PCR-detectable MRD patients treated with a single treatment course with tositumomab.[79] Median PFS was 6.1 years, with 40 patients remaining in remission for 4.3 to 7.7 years and no cases of myelodysplastic syndrome observed. A SWOG study investigated chemoimmunotherapy with six cycles of CHOP chemotherapy followed 4 to 8 weeks later by tositumomab in 90 patients with previously untreated, advanced-stage FL.[81] The OR was 91%, including 69% CR; at median follow-up time of 5.1 years, the estimated 5-year OS was 87% and PFS was 67%, which 23% better than CHOP alone on previous SWOG protocols. Ibritumomab tiuxetan is a ^{88}Y-labeled anti-CD20 antibody that produced an OR of 74% and 15% CR in 57 FL patients refractory to rituximab.[82] Toxicity is primarily hematologic, with nadir counts occurring at 7 to 9 weeks and lasting approximately 1 to 4 weeks. The risk for hematologic toxicity increased with dose delivered and with degree of baseline bone marrow lymphoma involvement.[83] An acceptable safety profile was observed in relapsed patients with less than 25% lymphoma marrow involvement, adequate marrow reserve, platelets greater than 100,000 cells/μL, and neutrophils greater than 1500 cells/μL.

High-Dose Therapy as Consolidation of First Remission

The role of high-dose therapy (HDT) and autologous SCT (ASCT) in FL patients during first remission has been explored in phase II trials[84,85] and in three phase III randomized trials.[86-88] The GLSG trial[86] recruited 307 previously untreated patients up to 60 years of age; patients who responded after induction chemotherapy with two cycles of CHOP or MCP (mitoxantrone, chlorambucil, and prednisone) were randomized to receive ASCT or IFN-α maintenance. Among 240 evaluable patients, the 5-year PFS was 64.7% for ASCT, and 33.3% in the IFN-α arm ($P < 0.0001$). Acute toxicity was higher in the ASCT group, but early mortality was below 2.5% in both study arms. Longer follow-up is necessary to determine the effect of ASCT on OS. In the Groupe Ouest Est des Leucemies Aigues et des Maladies du Sang (GOELAMS) study, 172 newly diagnosed advanced-stage FL patients were randomized either to CHVP (cyclophosphamide, hydroxydaunomycin, teniposide [Vumon], and prednisone) and IFN-α or to HDT followed by purged ASCT.[87] Patients treated with high-dose therapy had a higher response rate than those who received chemotherapy and IFN-α (81% versus 69%, $p = 0.045$) and a longer median PFS (not reached versus 45 months); however, because of an excess of secondary malignancies after transplantation, this did not translate into a better OS. A subgroup of patients with a significantly higher event-free survival rate after ASCT could be identified using the FLIPI. The GELF94 study enrolled 401 previously untreated advanced-stage FL patients who were randomized to receive CHVP plus IFN-α compared with four courses of CHOP followed by HDT with total body irradiation (TBI) and ASCT; OR rates were similar in both groups (79% and 78%, respectively), and 87% of eligible patients underwent ASCT. Intent-to-treat analysis after a median follow-up of 7.5 years showed no difference between the two arms for OS ($p = 0.53$) or PFS ($p = 0.11$). Long-term follow-up demonstrated no statistically significant benefit in favor of first-line ASCT in patients with FL, which the investigators conclude should be reserved for relapsed patients. A metaanalysis concluded that that HDT and ASCT does not improve overall survival in FL.[89] In view of these results, ASCT should be used in first remission only in the setting of clinical trials.

TREATMENT OF RELAPSED INDOLENT LYMPHOMA

The treatment options after relapse remain the same as for first-line therapy (see Table 79-5), and ideally, relapsed patients should be treated in clinical trials. Relapsed asymptomatic disease is not necessarily an indication for treatment, and patients can again be managed expectantly. A number of factors must be taken into account in planning therapy; it is not possible to define treatment at relapse without considering the goal of therapy (palliative versus potentially curative), performance status, previous therapy, response, and duration of response. Single-agent rituximab is approved for relapsed lymphoma and is widely used in this setting. A multicenter randomized trial in relapsed patients has demonstrated a survival advantage for chemoimmunotherapy with R-CHOP or

with CHOP followed by rituximab compared with CHOP alone, as well as a further benefit for rituximab maintenance therapy.[64] For younger patients who are suitable candidates for either HDT and ASCT or reduced-intensity conditioning (RIC) allogeneic transplantation, referral to a transplant center should be considered early to discuss the potential role and timing of transplantation. Best results are seen when transplantation is considered early in the course of disease, before patients become chemorefractory, and HDT and ASCT remain an effective treatment approach for younger patients with chemoresponsive-relapsed disease. SCT approaches must be considered in the context of the improving results that are being seen with salvage therapy alone.

The Role of Transplant in Relapsed Indolent Lymphomas

Unlike its use with aggressive lymphomas, the use of high-dose chemotherapy with autologous SCT in the treatment of indolent lymphomas has not yet been fully established. The rationale for considering transplantation is that the disease is incurable using standard approaches; young patients with indolent lymphomas will die of their disease, and promising results have been observed in a number of phase II studies.[90-92] Detection of MRD has been a useful surrogate marker for tracking long-term PFS in patients examining the autologous stem cells or serial samples after transplantation.[92-96] A major concern relates to the risk for development of secondary myelodysplasia/acute myeloid leukemia.[97] The European Bone Marrow Transplant Registry (EBMTR)–sponsored CUP study (conventional chemotherapy, unpurged, purged autograft) is the only prospective randomized trial to assess the role of autologous SCT in patients with relapsed FL.[98] The results of the study suggest a PFS and OS advantage of ASCT over conventional chemotherapy, with 4-year OS of 46% for the chemotherapy arm, versus 71% for the unpurged and 77% for the purged ASCT arms. The study was closed early because of slow accrual with 140 of the planned 250 patients accrued and only 89 randomized.

Novel Agents

A large number of novel approaches are being studied in FL patients. These include monoclonal antibodies, idiotype vaccines, immunomodulatory agents, and novel kinase inhibitors. Combinations of monoclonal antibodies are being explored, such as combining anti-CD20 with anti-CD22 antibodies.[99] Several new anti-CD20 monoclonal antibodies are being evaluated in FL patients refractory to rituximab. These include several humanized antibodies designed to have less infusion toxicity and improved effector function.[100,101] GA101 is the first type II, glycoengineered, and humanized monoclonal anti-CD20 antibody[102] to enhance the activity of rituximab. Kinases involved in the B-cell receptor–signaling pathway are logical targets for therapy in FL. Clinical trial data have been presented for three kinase inhibitors, which target PI3 kinase p110d,[103] BTK,[104] and SYK,[105] respectively. These agents are now being examined in combination with monoclonal antibodies and chemotherapy. Since a hallmark of FL is overexpression of BCL2, this protein is also a logical target for small molecule inhibitors that can diminish the antiapoptotic activity of BCL2. Clinical responses have been observed in a phase I study examining the efficacy of navitoclax in lymphoid malignancies,[106] and this agent and similar compounds are currently also being evaluated in ongoing clinical trials alone and in combinations.

Allogeneic BMT

There is a trend toward the increasing use of allogeneic SCT (aSCT) in the management of indolent lymphomas. In a report of the International Bone Marrow Transplant Registry (IBMTR), results after SCT are described for 904 patients with FL.[107] Among these patients, 176 underwent aSCT, 131 underwent ASCT using purged stem cells, and 597 had ASCT using purged autologous stem cells. The transplant-related mortality (TRM) in these three groups was 30%, 14%, and 8%, respectively; disease recurrence occurred in 21%, 43%, and 58%, respectively; and 5-year overall survival was 51%, 62%, and 55%, respectively. The use of regimens involving TBI was associated with increased TRM but decreased risk for relapse. The use of aSCT was associated with increased TRM but significantly lower risk for disease recurrence, in keeping with a graft-versus-lymphoma effect in this disease. Trends suggest that outcomes are improving; this is highly likely to continue with the increased use of RIC regimens that have become increasingly common since the time these IBMTR data were collated. Long-term PFS has been observed after aSCT, even in patients with refractory FL.[108] In 29 FL patients, 11 of whom had refractory disease, the nonrelapse mortality rate was 24% and there was a 23% incidence of relapse. The 5-year OS was 58% with 53% event-free survival. Patients who have relapsed after previous autologous SCT have very poor outcomes. The outcome following myeloablative allogeneic SCT of 114 such patients has been reported from the IBMTR.[109] The treatment-related mortality was 22%, and the probability of disease progression was 52% at 3 years.

The use of TBI conditioning regimens and achievement of CR at the time of allogeneic SCT were associated with improved outcome. The use of RIC regimens appears to be associated with improved outcome. In 20 such patients, only one treatment-related mortality occurred (due to fungal infection), and the 3-year PFS was excellent, at 95%.[110] The outcome following RIC transplant regimen incorporating alemtuzumab immunosuppressive therapy has been reported for patients with 81 patients with lymphoma, including 41 with low-grade FL, 37 with high- or intermediate-grade FL, and 10 patients with MCL, 31 of whom had relapsed following previous autologous SCT.[111] Patients received a conditioning regimen consisting of alemtuzumab, fludarabine and melphalan; they also received short-course cyclosporine as prophylaxis for graft-versus-host disease (GVHD). The use of this conditioning regimen was associated with a low incidence of GVHD, and the treatment-related mortality was decreased in patients with low-grade compared with higher-grade histology. The 3-year PFS was 65% for patients with low-grade lymphoma, 50% for patients with MCL, and 34% for higher-grade lymphoma ($p = 0.002$). Donor lymphocyte infusion (DLI) was given to 36 patients, 21 for relapsed or persistent disease and 15 for persistence of mixed chimerism. The use of DLI to treat relapse after allogeneic SCT is solely dependent on the existence of a graft-versus-lymphoma effect. In seven patients with FL and SLL who had relapsed after prior allogeneic SCT, six patients responded; in four of these patients, the CRs were maintained for 43 to 89 months. The effectiveness of DLI to treat relapse after allogeneic SCT provides very strong evidence for a graft-versus-lymphoma effect that can be exploited in indolent lymphomas.[111,112] The role of RIC allogeneic SCT has been evaluated by the Cancer and Leukemia Group B in a phase II study to evaluate the safety and efficacy in patients with recurrent low-grade B cell malignancies, including 16 patients with FL.[113] The 3-year TRM was 9%, and the 3-year OS was 81%. The incidence of grade II-IV acute GVHD was 29%, and the extensive chronic GVHD was 18%.

CHAPTER 80

MANTLE CELL LYMPHOMA

Michael Wang, Liang Zhang, Zhishuo Ou, Madhav V. Desai, Ken H. Young, Richard E. Champlin, Larry W. Kwak, and Jorge E. Romaguera

Mantle cell lymphoma (MCL) is a well-defined pathologic and clinical entity with an extremely variable clinical course. It is incurable using current approaches and has a poor prognosis after conventional chemotherapy when compared with other types of B-cell lymphomas. The major genetic feature of MCL is the presence of a t(11;14) translocation that results in the overexpression of cyclin D1 (CCDN1) in the tumor cells of virtually all patients. No standard treatment has been established to date; however, progress made towards elucidating the pathogenesis of MCL has led to novel approaches to therapy that have greatly improved patient outcomes.

DEFINITION AND HISTORY

Mantle cell lymphoma is classified as a subtype of B-cell lymphoma derived from CD5-positive antigen-naive pregerminal center B cells within the mantle zone that surrounds the normal germinal center follicles. Previously named *intermediate lymphocytic lymphoma, centrocytic lymphoma, lymphocytic lymphoma with intermediate differentiation,* and *marginal zone lymphoma,* MCL is now recognized as a distinct entity with a unique biology and aggressive clinical behavior.

EPIDEMIOLOGY

MCL represents approximately 6% (3% to 10%) of all non-Hodgkin lymphomas (NHLs) and accounts for 3000 to 4000 cases of lymphoma per year in the United States, with current median survival duration of up to 5 years. The median age at diagnosis is 68 years (range, 29 to 85 years), and the overall incidence of MCL is estimated to be 0.55 per 100,000 in the United States,[1] which increases with age. Given the relatively short median overall survival (OS), its prevalence is low, at 15,000 cases. Currently, there are no known etiologic agents for MCL.

CLINICAL FEATURES

The ratio of men to women diagnosed with MCL is about 4:1. The early symptoms usually include fever, heavy night sweats, unexplained weight loss, swelling of the lymph nodes, and splenomegaly. The typical presentation is that of a 64-year-old man with advanced disease who is asymptomatic (Table 80-1).[2] The spleen can be enlarged in 40% of patients, and 50% of patients can present with blood involvement, sometimes with an overt leukemic phase but more often with subclinical involvement, as detected by flow cytometry. Symptomatic gastrointestinal involvement occurs in 25% of MCL cases; at its most extreme, this is known as lymphomatous polyposis. Overall, gastrointestinal involvement can be detected in 90% of cases; half of these can be diagnosed only by panendoscopy and microscopic evaluation of random biopsies. Most cases are detected using colonoscopy.[3,4]

LABORATORY FEATURES

Morphologic Features

Histologically, MCL presents most frequently as a diffuse effacement of the lymph nodes, less frequently as nodules, and rarely as a mantle zone pattern, defined as >90% of the follicles presenting with preservation of the germinal center (Fig. 80-1).[5]

There are four cytologic variants of MCL. (1) Classic MCL is characterized by a monotonous population of small to intermediately sized lymphoid cells with slightly irregular nuclei, scant cytoplasm, and finely condensed chromatin. In some cases, the residual normal germinal center may be disrupted. (2) The small-cell variant is composed of small, round lymphocytes (which resemble chronic lymphocytic leukemia) and finely clumped chromatin. (3) The blastoid-cell variant is the most common and is characterized by large blastoid lymphocytes, appreciable nucleoli, and more abundant cytoplasm. (4) The pleomorphic variant is characterized by medium to large cells and prominent nuclei. The blastoid and pleomorphic variants are associated with a more aggressive clinical course. A rare monocytoid variant with features resembling marginal-zone B-cell lymphoma has also been reported.

Immunophenotypic Features

Immunophenotyping of MCL has revealed the positive expression of the B cell–associated antigens CD19, CD20, CD22, and CD79a; the aberrant expression of the T cell–associated antigens CD5 and CD43; and negative staining for CD7, CD8, and CD23. MCL stains are strongly positive for the antiapoptotic molecule BCL2 and negative for the germinal center markers CD10 and BCL6.[5] The diagnostic marker for MCL that is not encountered in other malignant lymphomas is the overexpression of cyclin D1, which is revealed most accurately in stains of formalin-fixed, paraffin-embedded lymph nodes or soft tissue.

Cytogenetic Features

The t(11;14)(q13;q32) translocation, which is characteristic of MCL and the central and primary event of lymphomagenesis, occurs in bone marrow at the pre–B-cell stage of differentiation when the B cell is initiating IG gene rearrangement with the recombination of the V(D)J segments.[6] The reciprocal chromosomal translocation involves the cyclin D1 (CCND1) gene on chromosome 11 and the IGH gene locus on chromosome 14. This results in increased expression of cyclin D1. A cell-cycle protein not normally expressed in lymphoid and myeloid cells, cyclin D1 promotes the transition from the G1 to the S phase of the cell cycle. In the rare cases of MCL in which cyclin D1 is not overexpressed, cyclin D2 or cyclin D3 is usually overexpressed,[7] suggesting that deregulation of other members of the highly conserved cyclin family may be an alternative

mechanism to cyclin D1 overexpression in MCL tumorigenesis. The transcription factor SOX-11 is highly expressed in these cyclin D1–negative MCL cases but absent in other types of mature B-cell lymphoma and thereby serves as a valuable biomarker for the differential diagnosis of MCL in these cases.

Although most cases of MCL have the conventional t(11;14)(q13;q32) chromosomal translocation, additional genetic events contributing to the progression of MCL have been clinically observed. In addition, low numbers of cells carrying the t(11;14) translocation have been found in the blood of 1% to 2% of healthy individuals without any evidence of disease.[8] Cytogenetic studies have revealed secondary genetic alterations (Table 80-2) that may be involved in the pathogenesis and progression of MCL and have shown that MCL has one of the highest levels of genomic instability among the malignant lymphoid neoplasms.[9] The analysis of primary MCL cells with relatively low-resolution conventional comparative genomic hybridization, high-resolution comparative genomic hybridization array, and single nucleotide polymorphism microarray combined with microarray gene-expression profiling studies has revealed that MCL has a characteristic profile of genomic alterations. In addition, the delineation of minimally altered regions has facilitated the identification of potential target genes (Table 80-2).[10-14]

Dysregulation occurs not only in the cell cycle, but also in the DNA damage–response and cell-survival pathways. The blastoid variant is associated with most of these genetic alterations. In addition, TP53 mutations, uniparental disomy involving TP53, INK4a/ARF homozygous deletions, and BMI1 amplifications are all known to contribute to MCL cell proliferation. Abnormalities in chromosome 17p have been observed in up to 26% of MCL cases[15] and have been associated with p53 mutations, which correlate with poor prognosis,[16] most likely owing to the impairment of the DNA damage–response pathway.

Biologic Pathways and Potential Therapeutic Targets

Comprehensive abnormalities identified in cell survival, DNA damage, cell-cycle regulation, and apoptosis pathways provide the biologic mechanisms responsible for the aggressive clinical behavior of MCL, its rapid relapse, and its short response to therapy. Its proliferation activity, which reflects these biologic mechanisms, is therefore believed to be the most valuable pathologic parameter for predicting the biologic behavior of MCL tumors.

A proposed model of MCL progression is depicted in Fig. 80-2.[6] Overall, CCND1 translocation is the primary or initial genetic event, followed by alterations in two major signaling pathways, INK4a/CDK4/RB1 and MDM2/TP53/P27. Studies indicate that secondary genetic alterations may reinforce the two major signaling pathways'

effects, which include further enhancing cell proliferation, facilitating evasion of apoptosis, reducing immune control, and promoting interactions with the tumor microenvironment through constitutive activation of the Wnt, hedgehog, PI3K/AKT/mammalian target of rapamycin (mTOR), B-cell antigen receptor (BCR), and nuclear factor kappa-B (NF-κB) signaling pathways, as well as TP53 mutation and BMI1 amplification (Fig. 80-3).[17] These altered molecular pathways in MCL—including the often constitutively activated PI3K/AKT/mTOR, Wnt, hedgehog, BCR, and NF-κB pathways—provide insight into its pathogenesis. The overexpressed cyclin D1 complexes with CDK4, and this has at least two important downstream effects. The cyclin D1-CDK4 (or CDK6) complex leads to phosphorylation of the retinoblastoma gene RB1, with the net result (through the release of elongation factor 2 [EF2] transcription factors) being the progression of the lymphoma cells into S phase. The cyclin D1-CDK4 complex may also neutralize the ability of the CDK inhibitor p27 to induce G1 cell-cycle arrest.

Table 80-2 Main Genetic Anomalies, Including Losses and Gains, in Mantle Cell Lymphoma

	Main Genetic Losses	Main Genetic Gains

Terms in parentheses are potential target genes.

One of these secondary alterations is the mutation of the ataxia-telangiectasia mutant (ATM) gene, which is seen in about 40% of MCL cases. ATM inactivation facilitates genomic instability in lymphoma cells by impairing their response to DNA damage. Also, PI3K, which is encoded by ATM, is a key kinase in this pathway. Notably, the PI3K-AKT pathway is upstream of mTOR, which is in turn upstream of cyclin D1, p27, and other regulatory proteins.[18,19]

Other genetic alterations affect two major signaling pathways: the Wnt canonical pathway (WCP) via β-catenin, which is important for normal cell growth and development, and an alternative pathway leading to JNK activation. Activation of β-catenin is a relatively frequent aberration in MCL, and several Wnt members are consistently overexpressed in MCL.[20]

The hedgehog signaling pathway can also be altered in MCL. This pathway is one of the key regulators of animal development, and sonic hedgehog (SHH) is the well-known ligand of the vertebrate pathway. SHH-GLI signaling molecules such as PTCH, SMO, GLI1, and GLI2 are expressed in human MCL cell lines and in primary MCL cells from patients. Downregulation of GLI transcription factors has been shown to significantly decrease the proliferation of MCL cells and increase the susceptibility of MCL cells to chemotherapy.[21]

Another pathway involved in the pathogenesis of MCL is the ubiquitin-proteasome pathway, the major nonlysosomal pathway through which intracellular proteins are degraded. By stabilizing the promoters of cyclins and repressors of CDK, proteasome inhibition leads to cell-cycle arrest and the induction of apoptosis.[22] This pathway plays an essential role in the activation of NF-κB by degrading its inhibitory protein, I-κB.[23] The NF-κB signaling regulates transcription factors that activate numerous genes involved in cell survival, apoptosis, and cell migration. Its persistent activity is associated with tumor formation, tumor growth, metastasis, and drug resistance in many cancer types, including B-cell lymphoma. Current therapeutic efforts to inhibit this central "switch" include using small molecules to block selected targets in the pathway.[24] Studies show that

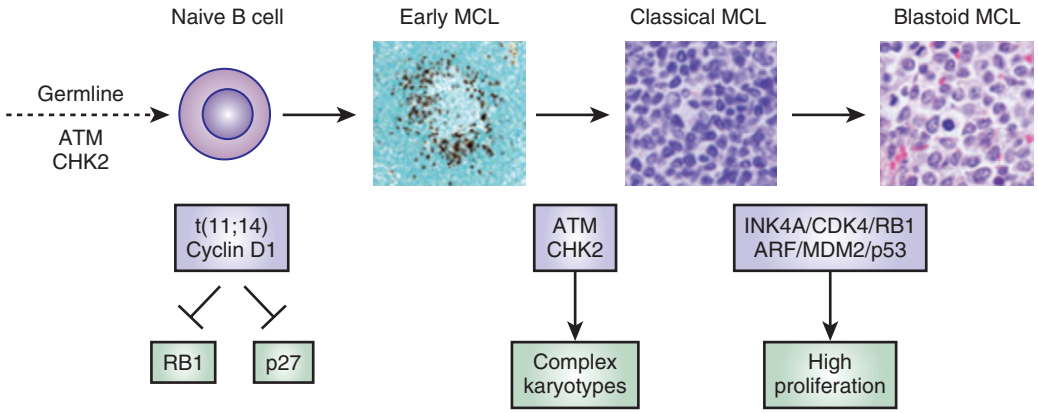

Figure 80-2 PROPOSED MODEL OF MOLECULAR PATHOGENESIS IN THE DEVELOPMENT AND PROGRESSION OF MANTLE CELL LYMPHOMA. The presence of ataxia-telangiectasia–mutated (ATM) or cell cycle checkpoint kinase 2 (CHK2) inactivating mutations in the germline of some patients suggests that they may facilitate the development of the tumor. The t(11;14) translocation occurs in an immature B cell and leads to the constitutive deregulation of cyclin D1 and early expansion of tumor B cells in the mantle zone areas of lymphoid follicles. Acquired inactivation of DNA damage response pathways may facilitate additional genetic alterations and the development of classical mantle cell lymphoma. Further genetic alterations may target genes of the cell cycle and senescence regulatory pathways, leading to more proliferative and aggressive variants of MCL.

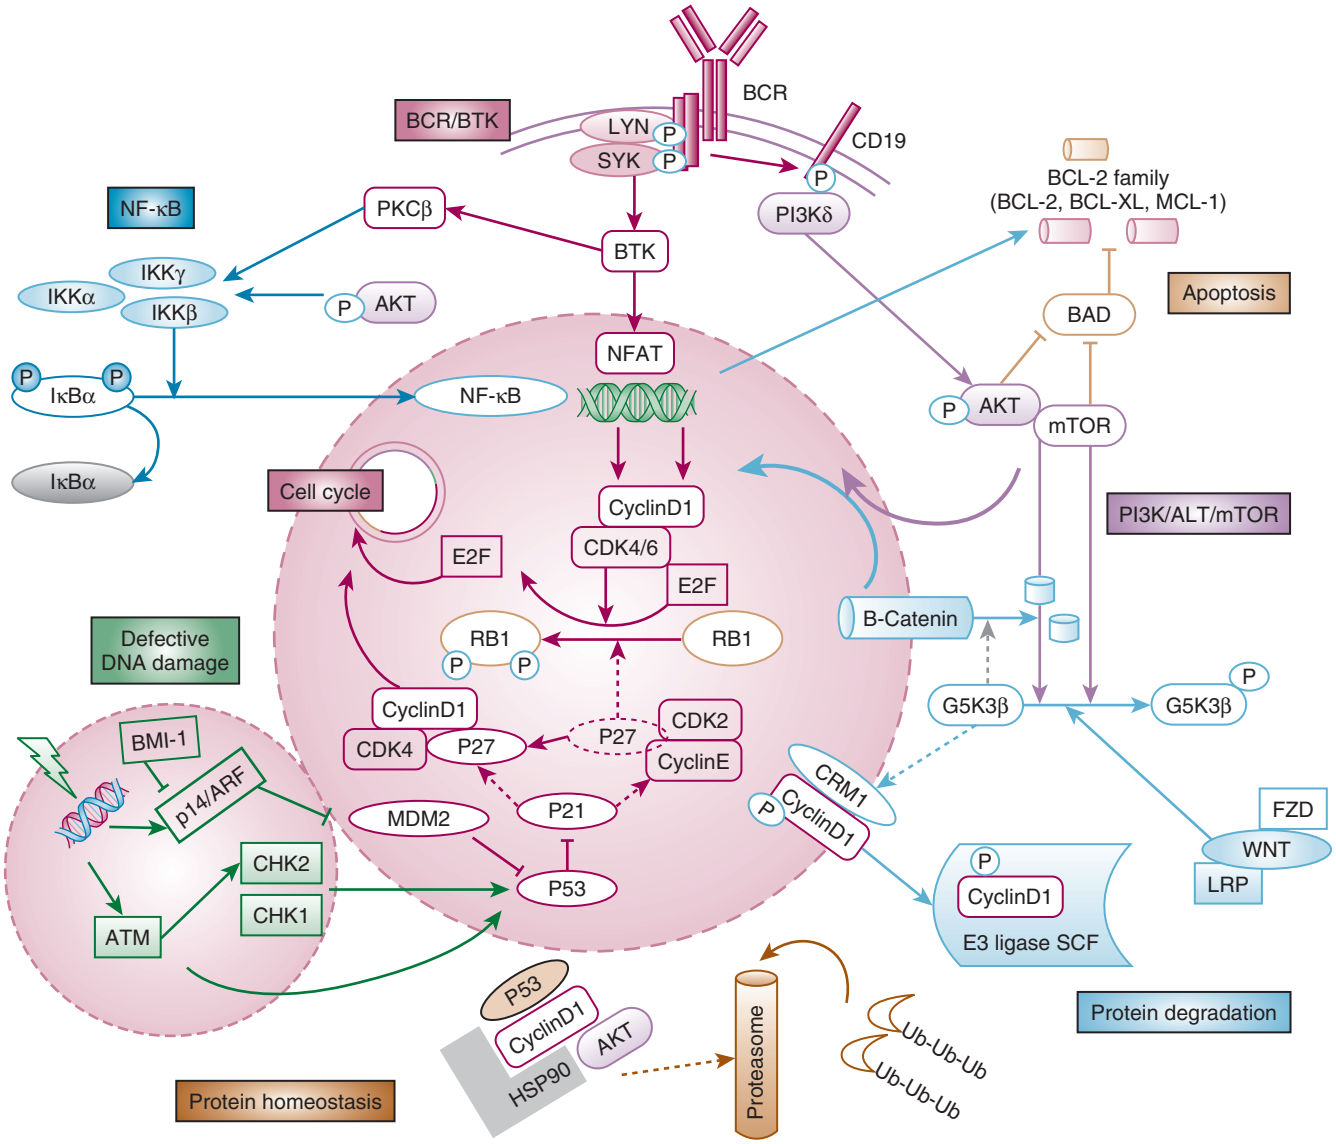

Figure 80-3 THE SIGNALING PATHWAYS CONTRIBUTING TO MANTLE CELL LYMPHOMA PATHOGENESIS. CCND1 translocation is the main primary or initial oncogenic event, which is followed by alterations in two major signaling pathways, the RB1 and P27 pathways. The secondary alterations may target genes functioning in these two major signaling pathways to further enhance MCL cell proliferation, which may be involved in the constitutive activation of BCR, Wnt, PI3K/AKT/mTOR, NF-κB, NFAT, HSP90, ATM, and other genes.

proteasome inhibitors, such as bortezomib (first generation) and carfilzomib (second generation), can be a novel approach for patients with relapsed/refractory MCL.[25,26]

Recent studies have reported constitutive activation of BCR signal transduction in MCL.[27] The lymphomagenesis of MCL is inseparable from B-cell development, because MCL is a type of B-cell lymphoma. Although the different subtypes of MCL have their own characteristics, BCR is associated with the pathogenesis of various subtypes of MCL, in most cases because BCR plays a key role in the process of B-cell differentiation and development. Many clinical studies have targeted BCR-associated kinases, including spleen tyrosine kinase (Syk), Bruton tyrosine kinase (Btk), and protein kinase C-beta (PKC-β). Intriguingly, Btk, a member of the Tec family of nonreceptor protein tyrosine kinases, has a well-defined role in the constitutively activated BCR signaling pathway in MCL. Clinical observations imply that Btk inhibition is a novel therapeutic approach in MCL. It is noteworthy that a recent phase I study of the novel small molecule PCI-32765, an irreversible Btk inhibitor, blocked B-cell activation and had antitumor activity in B-cell malignancies, including MCL, with favorable safety data.[28]

Recent molecular and genetic studies have revealed a subset of approximately 20% of MCL cases that have a relatively indolent clinical course. Prognosis in these patients is not affected by delaying initial therapy. These patients are clinically asymptomatic, their cases pathologically mimic low-grade B-cell lymphomas, and they usually present with leukemic phase or non-nodal involvement. Biologic mechanisms to explain this different clinical presentation have not yet been elucidated in this subset of cases.

DIFFERENTIAL DIAGNOSIS

The immunophenotype of MCL has some similarities to that of chronic lymphocytic leukemia (CLL) or small lymphocytic lymphoma (SLL) in that the lymphoma cells strongly express surface immunoglobulins M and D (IgM and IgD) and B cell–associated antigens CD19 and CD20 and aberrantly express the T-cell antigen CD5. Staining for B-cell antigens and Ig is stronger in intensity and more frequent in MCL than in CLL or SLL. In contrast to CLL or SLL cells, MCL cells express FMC7 and typically do not express

CD23. Similar to follicular lymphoma cells, MCL cells express CD20 and BCL2, but MCL cells do not express CD10 and BCL6, which are commonly expressed in follicular lymphoma cells.[5] This is because most MCL cases do not originate from the germinal-center B cells but from naive B cells in the mantle zone of the follicle. More important, almost all cases of MCL overexpress cyclin D1, a constant and highly specific biomarker seen in MCL but not in other types of lymphoma, in association with genetic rearrangement of the BCL1 locus.

Composite MCL and other composite lymphomas have also been recently reported. The composite components include follicular lymphoma, marginal zone lymphoma, CLL, SLL, Hodgkin lymphoma, plasmacytoma, and plasma cell myeloma. In these cases, the two different types of lymphoid neoplastic cells demonstrate their unique morphologic, immunophenotypic, and genetic features. Although molecular studies have shown clonal unrelatedness in some of these composite cases (CLL and SLL), a common clone-specific IGH rearrangement has been demonstrated in several composite cases of MCL with follicular lymphoma, marginal zone lymphoma, Hodgkin lymphoma, and plasmacytoma. These findings suggest that two lymphoid neoplasms may evolve from a single malignant clone, resulting in two morphologically, immunophenotypically, and genetically distinct lymphomas. A comprehensive morphologic and immunophenotypic study is required for an accurate differential diagnosis.

THERAPY

Frontline Therapy

MCL is still considered incurable. Because most patients present with advanced disease, most also require systemic therapy. Current strategies involve the intensification of therapy, with or without consolidation with stem cell transplantation (SCT). As novel drugs are discovered to be effective in the relapse/refractory setting, they are likely to be added to the current upfront combination chemotherapy strategies.

Doxorubicin-Containing Chemotherapy

MCL is responsive to doxorubicin-containing chemotherapy, but the complete remission (CR) rates are only 30% to 40%, the duration of response is 10 to 12 months, and the median duration of survival is 3 to 4 years, all of which are lower than these endpoints reported in other lymphomas.[29]

Fludarabine Alone or in Combination

Fludarabine is a purine analog that inhibits DNA synthesis by interfering with ribonucleotide reductase and DNA polymerase. In patients with previously untreated MCL, it yielded an overall response (OR) rate of 41% and a CR rate of 29%.[30] The median OS in that study was 2 years. However, fludarabine therapy is fraught with concerns regarding the ability to subsequently collect autologous stem cells, if needed. It has been reported that previous fludarabine therapy interferes with the quality of stem cells harvested and increases the risk for myelodysplastic syndrome/acute myeloid leukemia after autologous SCT.[31]

Importance of Rituximab

The anti-CD20 monoclonal antibody rituximab is the most important addition to the frontline treatment of lymphomas, including MCL. Rituximab alone produces a 38% response rate in patients with untreated MCL, results in a median response duration of 1.2 years, has very little hematologic or nonhematologic toxicity, and can be used in selected patients who would otherwise not tolerate cytotoxic therapy, thus prolonging and improving their quality of life.[32] Rituximab improves both the response and duration of response when combined in the frontline and relapse settings.[33-36] If response to the frontline therapy is less than complete, the role of additional doses of rituximab has not been proven.[37] In addition, a metaanalysis has suggested that rituximab might improve OS.[36] In patients with blood involvement, the first dose of rituximab should be delivered with caution because of the risk for tumor lysis syndrome or cytokine-release syndrome. If necessary, the first chemotherapy cycle can be given without rituximab to avoid these potential complications. The role of rituximab as an agent for in vivo purging of malignant cells in the blood and marrow has been documented.[38,39] Whether maintenance therapy with periodic infusions of rituximab prolongs OS over retreatment upon clinical or molecular recurrence has not yet been determined.

Rituximab-HyperCVAD

The OS rate is poor in patients with MCL who receive conventional chemotherapy. Thus intense chemoimmunotherapy without consolidation SCT is a potential therapeutic option. Romaguera and colleagues[40] reported on a prospective phase II study of rituximab in combination with hyper-CVAD (fractionated cyclophosphamide, vincristine, doxorubicin [Adriamycin], and dexamethasone) (R-hyper-CVAD), alternating with rituximab in combination with high-dose methotrexate-cytarabine (ara-C) (R-MA) in untreated patients with diffuse and nodular MCL and their blastoid variants. Of the 97 patients who were treated, 97% responded and 87% achieved a CR. At 10 years of follow-up (median follow-up, 8 years), the median OS time for all patients had not been reached, and the median time to treatment failure (TTF) for all patients was 4.6 years, without a plateau in the curves. For a group of patients age 65 years or younger, the median OS time had not been reached, and the median TTF was 5.9 years. Multivariate analysis revealed pretreatment serum levels of β_2 microglobulin, International Prognostic Index (IPI) score, and mantle cell IPI (MIPI) score as predictive of both OS and TTF. The study concluded that intense chemoimmunotherapy without SCT is effective for untreated aggressive MCL.[40]

The Importance of Cytarabine

Several studies have suggested that cytarabine significantly improves response to chemotherapy. These include, among others, a study in which a regimen consisting of dexamethasone, high-dose cytarabine (ara-C), and cisplatin (Platinol) (DHAP) further cytoreduced tumors that were not responding to cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), and prednisone (CHOP)[41] before autoSCT. Results of a more recent trial[42] showed that high doses of cytarabine significantly improved the results of an autoSCT-containing regimen when compared with identical prior historical data without cytarabine. In the latter study, rituximab was also added to the frontline therapy, but rituximab alone cannot likely account for the impressive results. Thus high doses of cytarabine are also an important component of intense non-SCT regimens.[43]

Intense Chemotherapy With or Without Stem Cell Transplantation

Several studies have intensified conventional therapy and/or incorporated consolidation high-dose chemotherapy followed by SCT as part of the frontline therapy. As seen in Table 80-3, more intense chemotherapy combinations have produced better rates of CR and longer durations of response.[44-46] Whether consolidation with SCT is needed as part of the frontline therapy is not clear, because intense chemoimmunotherapy regimens without consolidation SCT have produced similar results.[46]

Among conventional chemotherapeutic options, reported regimens include nucleoside analogues, particularly the R-FCM

Table 80-3 Therapy Results for Untreated Mantle Cell Lymphoma in More Than 20 Patients

Study	Regimen	Age (years)	No. of Patients	CR/CRu (%)	Outcome	Median Follow-Up (months)

§Patients with molecular recurrence treated with rituximab and not counted as events.

(rituximab, fludarabine, cyclophosphamide, and mitoxantrone) regimen.[34] Of note is the bifunctional alkylating agent bendamustine, which, in combination with rituximab, has moved quickly to the frontline setting and shown similar efficacy as R-CHOP (rituximab, cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone), with less toxicity, in a multiinstitutional prospective randomized trial.[56]

Risk for Central Nervous System Disease

There is no consensus on the risk for central nervous system disease in patients with MCL or the need for prophylaxis. Studies have reported a 4% incidence of central nervous system disease in patients with MCL and a 5-year actuarial risk of 26%.[57-59] Possible risk factors mentioned in these studies include the presence of blastoid cytology and an elevated proliferation rate.

Minimal Residual Disease

Current molecular techniques allow for the detection of 1 in 10^4 to 1 in 10^6 MCL cells, although the methodology used is currently not uniform among researchers. A recent report suggested a correlation between molecular recurrence and clinical recurrence,[39] a relationship used in a recent trial as a basis for preemptive treatment with rituximab before any clinical evidence of recurrence was detected.[42] However, other researchers have not seen this correlation, because the sensitivity of their molecular tests differed.[60]

THERAPY FOR RECURRENT AND REFRACTORY DISEASE

The inherent resistance of MCL to conventional chemotherapy is evident at relapse. Table 80-4 shows a summary of most reported single-agent and combination chemotherapy trials in MCL. Among the studies of salvage therapies, several successful ones have recently exploited their biologic insights.

Proteasome Inhibitors

Bortezomib, a first-in-class reversible proteasome inhibitor, has been shown to produce a 31% to 50% response rate as a single-agent therapy and has been approved by the U.S. Food and Drug Administration (FDA).[81,82] Salinosporamide A, a second-generation proteasome inhibitor, is a natural product that has significant effects on the proteasome and provides more potent and durable proteasome inhibition than does bortezomib.[83] Carfilzomib, another second-generation proteasome inhibitor, selectively and irreversibly disables the chymotrypsin-like activity of the proteasome.[84] Both salinosporamide A and carfilzomib hold promise for relapsed or refractory MCL. In addition, carfilzomib has been shown to be effective in multiple myeloma.

Zhang and colleagues[85] investigated the therapeutic efficacy of carfilzomib in MCL in vitro and in vivo and showed that carfilzomib inhibited the growth of not only the MCL cell lines but also freshly isolated MCL cells from patients in a dose-dependent manner. Of note, carfilzomib also inhibited the proliferation of PMA/ionomycin-activated or anti-CD3/anti-CD28 monoclonal antibody–activated

cells but not resting peripheral blood mononuclear cells (PBMCs) from healthy donors. Flow cytometry using fluorescence-labeled annexin V and propidium iodide showed that carfilzomib induced apoptosis in both the cell lines and primary MCL cells in a time- and dose-dependent manner. Notably, carfilzomib did not induce apoptosis of normal PBMCs.

Carfilzomib was effective and therapeutic in an MCL mouse model established in severe combined immunodeficient (SCID) mice. Tumor growth was significantly inhibited after carfilzomib treatment compared with vehicle control, and the survival time of tumor-bearing mice was significantly prolonged in the treatment group. Western blot analysis showed that apoptosis of MCL cells was induced via the activation of caspase cascades and the PARP pathway. Pretreatment of cells with a pan-caspase inhibitor (z-VAD) but neither a caspase-8 inhibitor (z-IETD) nor a caspase-9 inhibitor (z-LEHD) alone completely blocked carfilzomib-induced apoptosis. The authors concluded that carfilzomib inhibited MCL cell growth and induced apoptosis via a caspase-dependent signaling pathway both in vitro and in vivo.[85]

Btk Inhibitor

Activation of the BCR signaling pathway contributes to the initiation and maintenance of B-cell malignancies. The Btk inhibitor PCI-32765 blocks B-cell activation and has antitumor activity in B-cell malignancies, including MCL, with favorable safety data.[86] PCI-32765, similar to other Btk inhibitors, was designed to inhibit Btk activation by selectively interacting with an ATP-binding site in the tyrosine kinase domain, preventing Btk phosphorylation and activation. PCI-32765, an orally bioavailable, selective, and irreversible inhibitor, was shown to block signaling downstream of Btk and completely and irreversibly inhibit B-cell activation.[87] Findings from a novel study imply that PCI-32765 inhibits MCL cell proliferation and chemokine secretion and interferes with MCL cell actin polymerization, highlighting the importance of BCR signaling and Btk in MCL and explaining the effect of the Btk inhibitor PCI-32765 on patients with MCL.[88] In that study, PCI-32765 effectively inhibited phospho-Btk, leading to reduced MCL cell growth. PCI-32765 also induced MCL cell apoptosis in a dose- and time-dependent manner in both MCL cell lines and primary cells.

A recent phase I study in patients with relapsed/refractory B-cell malignancies showed that the Btk inhibitor PCI-32765 is highly active and well tolerated. No cumulative toxicity was noted with a treatment duration of more than 6 months.[28] More recently, preliminary results of an ongoing phase II study of single-agent PCI-32765 in relapsed or refractory MCL have become available. In that study, PCI-32765 was administered orally at 560 mg daily (in continuous 28-day cycles) until disease progression. Bortezomib-naive and bortezomib-exposed cohorts were evaluated separately. Tumor response was evaluated every two cycles and classified by 2007 NHL International Workshop Group (IWG) criteria. A total of 48 (29 bortezomib-naive, 19 bortezomib-exposed) patients were enrolled and initiated treatment on study PCYC-1104 between February 16,

2011, and July 20, 2011. The median age is 67 years (62-72), and the median number of prior treatment regimens is two (range, one to five). Of the total patients, 24 (12 bortezomib-naive, 12 bortezomib-exposed) have undergone at least one follow-up tumor assessment and are evaluable for efficacy. Treatment has been well tolerated. No patients have discontinued treatment because of adverse events. The objective response rate (ORR) by IWG criteria is 67% (16/24); in the bortezomib-naive cohort, the ORR is 58% (7/12) and 75% (9/12) in the bortezomib-exposed cohort. To date, 35/39 patients remain on PCI-32765. Preliminary data from this phase II trial suggests that the potent Btk inhibitor PCI-32765 is well tolerated and induces a high rate of objective responses in patients with relapsed or refractory MCL. A phase III trial entitled "Safety and Efficacy of PCI-32765 in Subjects With Relapsed/Refractory MCL" is ongoing.[89] These preliminary results suggest that Btk inhibition is a novel therapeutic approach in MCL.

New Class of mTOR Inhibitors

mTOR is a key element of the PI3K/AKT pathway. Temsirolimus is a promising mTOR inhibitor that has been shown to produce a 38% OR rate.[73] Everolimus, an oral derivative of rapamycin, was shown to yield a 32% OR rate in patients with relapsed or refractory MCL.[90]

Flavopiridol: Cyclin D Kinase Inhibitor

Single-agent therapy with the cycline D kinase (CDK) inhibitor flavopiridol has not been effective, probably because of its schedule dependency. Recent research using flavopiridol in combination chemotherapy with a specific schedule suggests this is a promising approach.[56]

Immunomodulatory Drugs

Lenalidomide is an oral, antiangiogenic, antiproliferative immunomodulatory agent, and phase II studies of single-agent lenalidomide in lymphoma have yielded promising results, with 13% to 20% CR rates in relapsed or refractory MCL.[91,92] A phase I study demonstrated that when combined with rituximab, the combination therapy is well tolerated. Among 46 patients in a phase II trial, the ORR was 56.5%, the CR rate was 34.8%, and the PR rate was 21.7%. The median response duration was 18.9 months. The median progression-free survival was 12.4 months, and the median overall survival was 24.3 months. Oral lenalidomide plus rituximab is well tolerated and highly effective in patients with relapsed/refractory MCL.[93,94]

Stem Cell Transplantation

Since second and later remissions are predictably brief, SCT deserves consideration after cytoreduction with salvage chemotherapy. Unfortunately, relapsed or refractory MCL recurs after high-dose chemotherapy followed by rescue of autologous stem cells.[48,49,51-55] The current consensus is that the best result with the longest duration of disease control in the relapse setting is consolidation of a response, preferably a CR, with allogeneic SCT, based on evidence of graft-versus-lymphoma activity in MCL. A reduced-intensity allograft has been shown to produce progression-free survival (PFS)/event-free survival (EFS) rates of 40% to 80% and OS rates of 55% to 86% after a median follow-up of 2 to 3 years, with a 5% to 30% rate of acute graft-versus-host disease and up to a 24% treatment-related mortality rate.[95-99]

In addition, cure fractions may be emerging in patients who had received rituximab-containing autologous SCT in first remission and in patients who had received nonmyeloablative SCTs for relapsed or refractory MCL. After analysis of the results of long-term transplantation experience in patients with MCL, rituximab has been found to improve the outcome of patients undergoing autologous SCT and facilitated the effectiveness and durability of disease control in patients undergoing nonmyeloablative SCTs.[100]

Radioimmunotherapy Plus Chemotherapy

MCL is very sensitive to radiotherapy. Because the disease is advanced at presentation in a great majority of patients, radioimmunotherapy is an option worth exploring. The use of iodine I^{131}tositumomab as part of frontline therapy before any chemotherapy has been reported.[101] In 25 patients, the OR rate was 88%, the CR rate was 50%, and the molecular remission rate was 46%, all after just one dose of the radioimmunoisotope and before the start of CHOP chemotherapy. The median EFS duration was 21.6 months.

In the relapsed/refractory setting, single-agent ibritumomab tiuxetan-^{90}yttrium has resulted in a 41% OR rate and a 29% CR/CR, unconfirmed (CRu) rate but with a short time to progression of 5 months.[102] In another study in the relapsed/refractory setting, Gopal and colleagues[103] showed that radioimmunotherapy cytoreduced the tumor and was consolidated with high doses of cyclophosphamide and etoposide, followed by myloablative doses of iodine I^{131}tositumomab, resulting in a 100% OR rate, a 91% CR rate, and a 61% 3-year PFS rate.[103] Other researchers explored the use of standard doses of ibritumomab tiuxetan-^{90}yttrium as part of the preparative regimen for autoSCT in 41 patients with relapsed MCL and reported a 2-year OS rate of 90% and a 2-year PFS rate of 70% after a median follow-up of 18.4 months.[104]

Wang and colleagues[105] conducted a phase II trial to evaluate the safety and efficacy of ibritumomab tiuxetan-^{90}yttrium in patients with relapsed/refractory MCL. Thirty-four patients with a median age of 68 years (range, 52 to 79 years) received the therapeutic dose. The patients had received a median of three prior treatment regimens (range, one to six treatment regimens), including those that contained rituximab ($n = 32$) and bortezomib ($n = 7$). Of the 32 patients with measurable disease, 10 (31%) achieved CR or partial remission (PR). After a median follow-up of 22 months (range, 2 to 72+ months), an intent-to-treat analysis revealed a median EFS duration of 6 months and an OS duration of 21 months. The median EFS duration was 28 months for those who achieved PR or CR and 3 months for those whose disease did not respond ($P < 0.0001$); the median EFS duration was 9 months for patients whose tumor measured less than 5 cm in the largest diameter before treatment and 3 months for those whose tumor measured 5 cm or more ($P = 0.015$). The single-agent activity of ibritumomab tiuxetan-^{90}yttrium and its favorable safety profile warrant its further development for the treatment of MCL.[105]

Lenalidomide Plus Rituximab

Rituximab, a chimeric anti-CD20 antibody, is associated with direct induction of apoptosis and antibody-dependent cell-mediated cytotoxicity with clinical efficacy in MCL. Lenalidomide, a novel immunomodulatory agent, sensitizes tumor cells and enhances antibody-dependent cell-mediated cytotoxicity. In a preclinical study, Zhang and colleagues[106] attempted to elucidate the mechanism of the lenalidomide-enhanced rituximab-mediated cytotoxicity of MCL cells. They found that lenalidomide and rituximab induced growth inhibition of both cultured and fresh primary MCL cells. Lenalidomide enhanced rituximab-induced apoptosis by upregulating phosphorylation of JNK, BCL2, and BAD; increasing the release of cytochrome-c; and enhancing activation of caspase-3, -8, and -9 and cleavage of PARP. In addition, lenalidomide activated natural killer (NK) cells and increased CD16 expression in $CD56^{low}CD16^{+}$ NK cells. Lenalidomide augmented the rituximab-dependent cytotoxicity of whole PBMCs but not NK cell-depleted PBMCs by 30%. Daily treatment with lenalidomide increased the number of NK cells by 10-fold in SCID mice, and the lenalidomide-rituximab combination decreased tumor burden and prolonged survival of the MCL-bearing

SCID mice. Taken together, these findings demonstrate that lenalidomide and rituximab have a synergistically therapeutic effect on MCL cells by enhancing apoptosis and rituximab-dependent NK cell–mediated cytotoxicity and may be an optimal combination in a clinical trial of relapsed/refractory MCL.[106]

Wang and colleagues[93] attempted to determine the maximum tolerated dose of lenalidomide plus rituximab in a phase I clinical trial and to evaluate the efficacy and safety of this combination in a phase II trial in patients with relapsed/refractory MCL. Four patient cohorts received escalating doses of oral lenalidomide daily on days 1 to 21 of each 28-day cycle. Intravenous rituximab was administered once a week for 4 weeks during the first cycle only. Patients were treated until disease progression or severe toxicity. Fifty-two patients were enrolled: 14 in phase I and 46 (including eight patients from the phase I portion) in phase II. Two patients experienced dose-limiting toxic events with lenalidomide at 25 mg daily. The maximum tolerated dose was 20 mg lenalidomide given daily on days 1 to 21 of each 28-day cycle, plus intravenous rituximab at 375 mg/m^2 for 4 weekly doses during the first cycle. In the phase II study, grade 3 to 4 toxicities included neutropenia (17% of cycles), lymphopenia (7% of cycles), and thrombocytopenia (5% of cycles). Only two episodes of febrile neutropenia occurred. In the phase II trial, the OR rate was 56.5%, the CR rate was 34.8%, and the PR rate was 21.7%. The median response duration was 18.9 months. The median PFS duration was 12.4 months, and the median OS duration was 24.3 months. All 13 patients who had received bortezomib therapy before enrollment achieved stable disease or better. These results demonstrate that oral lenalidomide plus rituximab is well tolerated and highly effective for patients with relapsed/refractory MCL.[93]

FUTURE DIRECTIONS

Prospects for patients with this incurable lymphoma have improved over the past decade as a result of current therapy and improvement in diagnostic tools and supportive therapy. In addition, newer therapies have been made available that might alter the OS of patients with disease recurrence. A recent study reported an improvement in OS duration from 2.7 years between 1975 and 1986 to 5.8 years between 1996 and 2004.[107] In that study, the authors concluded that the addition of doxorubicin and stem cell transplantation with rituximab, as well as improved patient care, most likely accounted for the longer survival. Another retrospective study of patients treated without intense initial chemotherapy and with watchful waiting for those with stable or indolent MCL reported a median OS duration of 5 years.[108] Determining whether intense therapy or a conservative approach will result in a longer OS duration will require additional studies. More important, it will require the accurate identification of subgroups of patients with MCL who will have better or worse prognoses. Only then can studies be compared more rationally and significant advances made in the management of MCL.

Most of the reported prognostic variables and models are retrospective and were devised with patients who received therapy in the form of a doxorubicin-containing regimen with or without rituximab. Molecular profiling has revealed a group of genes associated with proliferation that can identify patient subsets that differ by more than 5 years in median survival.[109] An immunohistochemical test for the proliferation antigen Ki-67 has also been shown to have prognostic value in a retrospective study of patients with MCL treated with a variety of regimens, most of which contained doxorubicin.[110] More recently, a five-gene model for predicting survival in MCL using frozen or formalin-fixed, paraffin-embedded tissue has been developed.[111] Other variables reported to be of prognostic importance are the pretreatment serum levels of β_2 microglobulin and lactate dehydrogenase, blastoid cytology, age, Ann Arbor stage, extranodal presentation, and constitutional symptoms.[2,43] The recently introduced MIPI uses four independent prognostic factors: age, performance status, lactate dehydrogenase level, and leukocyte count.[112] Fig. 80-4 shows survival curves using this model for the accurate stratification of patients with MCLs. Patients were classified according to the MIPI into low-risk (44% of patients, median OS not reached), intermediate-risk (35% of patients, 51 months OS duration), and high-risk (21% of patients, 29 months OS duration) groups. Retrospective applications of this model have shown some correlation with prognosis.[38,113]

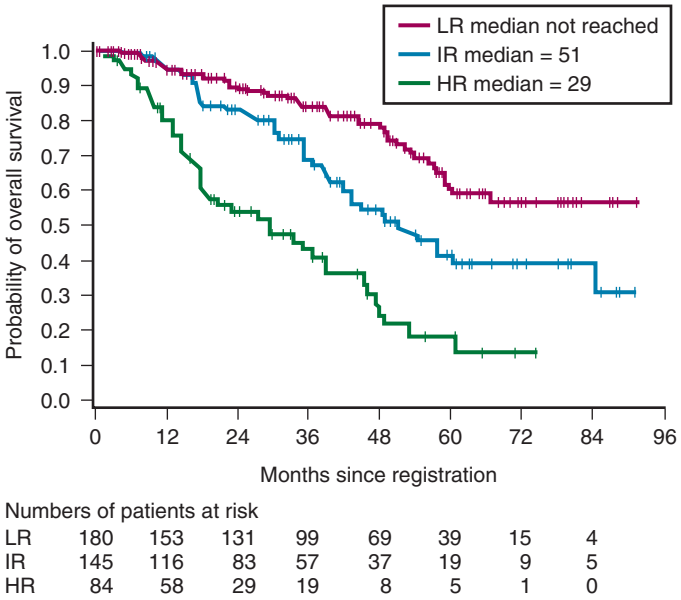

Figure 80-4 PROGNOSTIC GROUPS STRATIFIED ACCORDING TO THE MANTLE CELL INTERNATIONAL PROGNOSTIC INDEX.

With new therapies based on the knowledge of MCL biology and new prognostic models that can be used to tailor therapy and compare studies, the future of patients with MCL looks brighter.

CHAPTER 81

DIAGNOSIS AND TREATMENT OF DIFFUSE LARGE B-CELL LYMPHOMA AND BURKITT LYMPHOMA

Kieron Dunleavy and Wyndham H. Wilson

Diffuse large B-cell lymphoma (DLBCL) and Burkitt lymphoma (BL) are the most common types of aggressive B-cell lymphoma. Although they share many clinical and biological features, the approach to their management is different; therefore, an accurate histologic diagnosis is of utmost importance. There have been several recent therapeutic advances in the management of these diseases, and both DLBCL and BL have high cure rates with current treatment approaches. Therefore, it is imperative to promptly evaluate patients with these diseases and expeditiously institute appropriate therapy.

DIFFUSE LARGE B-CELL LYMPHOMA

Epidemiology

Diffuse large B-cell lymphoma is the most prevalent histologic subtype of non-Hodgkin lymphoma (NHL) (of which there were more than 65,000 new cases in the United States in 2010) and comprises 30% to 40% of these diseases.[1,2] Although the median age at diagnosis is in the seventh decade of life, DLBCL affects children and adults of all ages, and it is slightly more common in males than females. Although the etiology of DLBCL is unknown in most cases, it can arise from transformation of an indolent lymphoma. A history of immunodeficiency is a significant risk factor, and individuals who are HIV positive have a 100 times higher incidence of developing DLBCL over those who do not have HIV.

Pathobiology

The pathobiology of DLBCL is very diverse, and within DLBCL, there are several morphologic variants that include centroblastic, immunoblastic, T-cell rich or histioctye-rich, and anaplastic subtypes, and progress in molecular profiling is further advancing this taxonomy. There are also several clinical-pathologic variants of DLBCL. Primary mediastinal B-cell lymphoma (PMBL), for example, commonly presents in young women and usually remains localized to the mediastinum (Fig. 81-1). Primary central nervous system lymphoma (PCNSL) is another rare subtype of DLBCL that rarely disseminates to extraneural sites and is much more commonly observed in HIV-positive individuals. It is important to recognize that DLBCL can also arise as a result of histologic transformation from an indolent lymphoma. Although this differentiation may not affect treatment choice initially, it will affect prognosis and natural history and therefore needs to be recognized at diagnosis.

The neoplastic cells of DLBCL express pan B-cell markers, including CD20, and surface or cytoplasmic immunoglobulin is often demonstrated. CD10, BCL6, and IRF4/MUM1 are variably expressed, and the proliferation index as measured by Ki67 staining is typically high. Approximately 30% of cases show abnormalities involving the *BCL6* gene, and translocation of the *BCL2* gene—a hallmark of follicular lymphoma—is present in 20% to 30% of cases. Approximately 10% of cases of DLBCL harbor a t(8:14) MYC translocation, and recently, several groups have demonstrated that this confers a much worse prognosis compared with MYC-negative cases when CHOP-type (cyclophosphamide, doxorubicin [Novantrone], vincristine [Oncovin], and prednisone) regimens are used.

Recently, gene expression profiling has defined a new molecular taxonomy for DLBCL. Morphologically indistinguishable tumors can show marked heterogeneity in gene expression, and these patterns of expression may be classified into signatures that correspond to the cellular origin of the lymphoma according to its stage of B-cell differentiation; on the basis of these signatures, DLBCL can be divided into at least three different subtypes: germinal center B-cell (GCB)–like, activated B-cell (ABC)–like, and primary mediastinal B-cell lymphoma (PMBL). Patients with GCB DLBCL have a significantly better survival than patients with ABC DLBCL after immunochemotherapy.

Clinical Features

The clinical presentation of DLBCL is variable and depends on a number of factors, including histology, patient age, and immune status. The disease typically presents with lymphadenopathy that can range from relatively asymptomatic to causing pain (Fig. 81-2), causing organ compromise such as ureteral obstruction or spinal cord compression. The involvement of bone marrow (BM) is much less frequent than with indolent lymphomas and is present in approximately 20% of cases.

Patients may have constitutional manifestations from the production of inflammatory molecules and a variety of other cytokines and chemokines produced by the lymphoma cells or host tissues. Such manifestations include weight loss, malaise, fevers, night sweats, and loss of appetite. Of these, unexplained weight loss of more than 10% of body weight and temperature higher than 38° C as well as drenching night sweats are referred to as "B" symptoms.

Investigation

History and Physical Examination

Patients should be questioned about systemic symptoms, and their performance status should be assessed (Table 81-1). It is important to determine if there is a history of potential causative factors such as prior malignancy, chemotherapy or radiation treatment, or autoimmune or immunodeficiency diseases. A history of infection with or exposure to various pathogens, including HIV and hepatitis B and C, should be excluded. A detailed physical examination should be performed with particular attention to lymph node (LN) regions. Skin involvement by DLBCL is rare (Fig. 81-3).

An accurate histologic diagnosis is imperative to determine the patient's prognosis and treatment; therefore, the single most important diagnostic test is a properly evaluated and technically adequate excisional tissue biopsy. With few exceptions, fine-needle aspiration is inadequate for diagnosis. Aggressive lymphoma should be diagnosed by an experienced hematopathologist familiar with the nuances and pitfalls of lymphoma diagnosis.

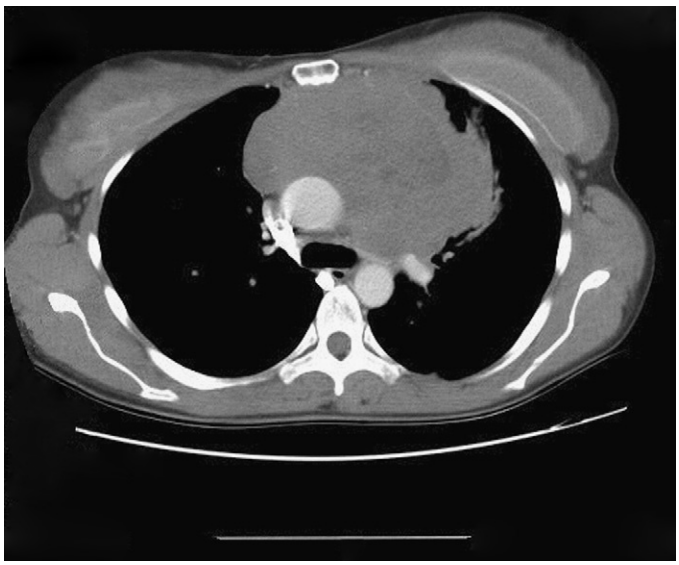

Figure 81-1 COMPUTED TOMOGRAPHY SCAN OF THE CHEST SHOWING A LARGE 17-CM ANTERIOR MEDIASTINAL MASS. A biopsy was consistent with primary mediastinal B-cell lymphoma.

Figure 81-2 COMPUTED TOMOGRAPHY SCAN OF THE ABDOMEN SHOWING A LARGE LEFT-SIDED PSOAS MASS. A biopsy was consistent with diffuse large B-cell lymphoma.

Table 81-1 Eastern Co-operative Group Performance Scale

Performance Status	Definition
0	Asymptomatic
1	Symptomatic but fully ambulatory
2	Symptomatic and in bed <50% of the day
3	Symptomatic and in bed >50% of the day
4	Bedridden

Laboratory Investigations

Laboratory tests should include a complete blood count; serum chemistry, including lactate dehydrogenase (LDH); and human immunodeficiency virus (HIV) and hepatitis serology tests (Table 81-2). The latter should be included because it is important to identify patients with active hepatitis and a history of hepatitis B because they will likely require treatment with antivirals, monitoring, or both (see box on Hepatitis B Prophylaxis and Therapy During Lymphoma Treatment). Epstein-Barr virus (EBV) viral loads may also be useful

Figure 81-3 INFILTRATION OF THE RIGHT LOWER ANTERIOR CHEST WALL WITH DIFFUSE LARGE B-CELL LYMPHOMA.

Table 81-2 Staging Evaluation for Diffuse Large B-Cell Lymphoma

All Patients	As Clinically Indicated
History and physical examination	Other viral studies
CBC and chemistry (including LDH)	CT or MRI of the head
HIV and hepatitis B and C serology	Body PET scan
Chest radiograph	Additional imaging
CT scan of the chest, abdomen, and pelvis	CSF evaluation by cytology or flow cytometry
BM aspirate and biopsy	Other tests indicated by results of staging

BM, Bone marrow; *CBC,* complete blood count; *CSF,* cerebrospinal fluid; *CT,* computed tomography; *LDH,* lactate dehydrogenase; *MRI,* magnetic resonance imaging; *PET,* positron emission tomography.

Hepatitis B Prophylaxis and Therapy During Lymphoma Treatment

There is a risk of hepatitis B reactivation both from chemotherapy and rituximab, and this is a potentially fatal complication. We check hepatitis serology (hepatitis B surface antigen [HBsAg], hepatitis B surface antibody [anti-HBs], and hepatitis B core antibody [anti-HBc]) in all patients at diagnosis. Patients with active hepatitis B receive antiviral medication and LFTs, and hepatitis B viral loads are monitored closely. Patients with a history of hepatitis B infection should either receive antiviral prophylaxis or have the hepatitis B viral load monitored very closely (ideally on each cycle) with a low threshold to commence antiviral medications.

in specific lymphomas such as posttransplant lymphoproliferative disorders (PTLDs) and EBV-positive DLBCL of elderly adults. An elevated LDH level has adverse prognostic implications for patients with DLBCL.

Imaging and Staging

It is important to determine sites of disease involvement; therefore, imaging studies should include computed tomography (CT) scanning of the chest, abdomen, and pelvis. The need for additional imaging studies such as magnetic resonance imaging (MRI) and fludeoxyglucose positron emission tomography (FDG-PET) scanning depends on the clinical presentation and sites of disease. For example, if central nervous system (CNS) involvement is highly suspected, evaluation of the head by CT or MRI may be indicated. Involvement of the bone is best evaluated by MRI and PET scans. Although PET scanning is widely used for lymphoma imaging, it does not have a validated role in the initial staging of aggressive NHL.[3] However, it may be a useful adjunct to CT for staging in certain clinical scenarios.

Because involvement of the BM may impact management, it should be assessed in all patients with DLBCL. Patients at increased risk of CNS involvement should undergo lumbar puncture with evaluation of the cerebrospinal fluid (CSF) by cytology and flow cytometry.[4] Specifically, clinical presentations with several extranodal sites and elevated LDH level as well as particular sites such as the testis and BM are associated with an increased risk of CNS disease, and intrathecal prophylaxis should be considered (see box on Intrathecal Prophylaxis in Diffuse Large B-Cell Lymphoma).[5]

DLBCL is staged according to the Ann Arbor staging system (Table 81-3), which was originally developed for Hodgkin lymphoma (HL). However, because of the heterogeneity and hematogenous pattern of dissemination in NHL, in contrast to contiguous LN spread with HL, the staging system has more limited value. At the same time, important modifications to the Ann Arbor staging system made at the Cotswold Conference have made it more applicable to NHL.[6]

Table 81-3 Ann Arbor Staging System for Lymphomas

Stage*	Cotswold Modification of Arbor Classification
I	Involvement of a single LN region or lymphoid structure
II	Involvement of two or more LN regions on the same side of the diaphragm (the mediastinum is considered a single site, but the hilar LNs are considered bilaterally); the number of atomic sites should be indicated by a subscript (e.g., II_3)
III	Involvement of LN regions on both sides of the diaphragm: III_1 (with or without involvement of splenic hilar, celiac, or portal nodes) and III_2 (with involvement of paraaortic, iliac, and mesenteric nodes
IV	Involvement of one or more extranodal sites in addition to a site for which the designation E has been used

LN, Lymph node.
*All cases are subclassified to indicate the absence (A) or presence (B) of the systemic symptoms of significant fever (>38.0° C [100.4° F]), night sweats, and unexplained weight loss exceeding 10% of normal body weight within the previous 6 months. The clinical stage (CS) denotes the stage as determined by all diagnostic examinations and a single diagnostic biopsy only. In the Ann Arbor classification, the term *pathologic stage* (PS) is used if a second biopsy of any kind has been obtained, whether the result was negative or positive. In the Cotswold modification, the PS is determined by laparotomy; X designates bulky disease (widening of the mediastinum by more than one-third or the presence of a nodal mass >10 cm), and E designates involvement of a single extranodal site that is contiguous or proximal to the known nodal site.

Prognosis

To identify prognostic factors in NHL, an international project to correlate clinical variables and outcome in 2031 patients with untreated aggressive lymphoma was undertaken.[7] The following parameters were associated with inferior outcome: age older than 60 years, Ann Arbor stage III or IV disease, serum LDH level above normal range, Eastern Co-operative Oncology Group (ECOG) performance status of 2 or higher, and involvement of two or more extranodal sites. A clinical prognostic model, termed the International Prognostic Index (IPI), was developed using these five factors. In this model, 1 point was allocated for each feature and nicely stratified patients into four groups with 5-year survivals of 73%, 51%, 43%, and 26% for zero or one, two, three, and four or five risk factors, respectively, with CHOP-based treatment.[7] Based on this model, the IPI has become the standard in DLBCL for assessing clinical prognosis and treatment stratification within and comparison between clinical trials. Although it has yet to be fully revalidated in the rituximab era in prospective studies, a revised prognostic model for R-CHOP, termed Revised-IPI, was recently published based on a limited retrospective series (Table 81-4).[8]

Although not yet routinely performed in aggressive NHL, gene expression profiling is emerging as an important prognostic tool.[9-12] In DLBCL, overall survival is different in each group and superior in patients with the GCB compared with the ABC subtype. Using gene expression profiling, a molecular prognostic model of survival, independent of the IPI, has been developed for R-CHOP–treated DLBCL.[10] Although gene expression profiling is not routinely performed at diagnosis, several immunohistochemical models have been developed to predict GCB or non-GCB origin of the DLBCL.[13,14]

Intrathecal Prophylaxis in Diffuse Large B-Cell Lymphoma

In DLBCL, the role of intrathecal prophylaxis to prevent CNS recurrence is controversial and poorly studied, and there are several different approaches. Our approach is as follows. All patients at risk for CNS disease undergo a lumbar puncture at diagnosis, and CSF is checked by cytology and flow cytometry; if the results are positive, patients receive active treatment of the CNS. We administer intrathecal prophylaxis to all patients who fulfill either of the following criteria:

1. Two or more extranodal sites of disease involvement and an elevated LDH level
2. Certain extranodal sites of involvement that have been associated with an increased risk of CNS spread such as BM and testis

We use intrathecal methotrexate at a dose of 12 mg. We commence prophylaxis on cycle 3 day 1 and administer it on days 1 and 5 of cycles 3 through 6.

Table 81-4 Revised International Prognostic Index (R-IPI)*

No. of IPI Factors	IPI Score	Outcome	Overall Survival (%)
0	0	Very Good	94
1–2	1–2	Good	79
3, 4, or 5	3–5	Poor	55

From Sehn LH, Berry B, Chhanabhai M, et al: The revised International Prognostic Index is a better predictor of outcome than the standard IPI for patients with diffuse large B-cell lymphoma treated with R-CHOP. *Blood* 109:1857, 2007.
ECOG, Eastern Cooperative Oncology Group; *IPI,* International Prognostic Index; *LDH,* lactate dehydrogenase
*One point is given for the presence of each of the following characteristics: age older than 60 years, elevated serum LDH level, ECOG performance status ≥2, Ann Arbor stage III or IV, and more than two extranodal sites.

Although molecular profiling remains an experimental technique that is not widely available, it will likely help to improve pathologic diagnostic accuracy, predict outcome with greater precision, and help elucidate pathways of lymphomagenesis. This should lead to the identification of novel cellular targets, paving the way for more personalized therapy. The current integration of immunostaining and gene expression profiling into large prospective clinical trials is imperative to facilitate the investigation and development of new and useful prognostic models that may ultimately guide therapeutic choices.

Treatment

The mainstay of treatment for DLBCL is systemic chemotherapy; radiation treatment alone is inadequate and associated with high recurrence rates.[15] For early stage disease, whether or not radiation treatment adds benefit to chemotherapy has been controversial. Based on a randomized study that showed a survival advantage of limited course CHOP plus involved field radiation compared with full course CHOP in early stage (I/II) aggressive lymphoma, combined modality therapy became the standard.[16] However, longer patient follow-up showed a convergence of the overall survival curves because of late systemic relapses in the combined modality arm, thus reopening the debate on radiation.[16,17] In this regard, a prospective Groupe d'Etude des Lymphomes de l'Adulte (GELA) study randomized 576 elderly patients with favorable early stage aggressive lymphoma to receive CHOP alone (4 cycles) or CHOP plus radiation and found that combined modality therapy was not superior to chemotherapy alone.[18] Given these results and the improved outcome of R-CHOP, it is difficult to justify the routine use of radiation in early stage disease.

A possible exception to the omission of radiation, however, is in the treatment of primary mediastinal DLBCL (PMBL), depending on the chemotherapy regimen. In a study of 50 untreated patients with PMBL who received MACOP-B (methotrexate, ARA-C [Cytarabine], cyclophosphamide, Oncovin, prednisone, and bleomycin) followed by radiation, 66% had persistently positive gallium scans after chemotherapy, suggesting active disease. After consolidation radiotherapy, however, only 19% of patients had a positive gallium scan, and 80% were event free at 39 months of median follow-up.[19] This important study suggested that radiotherapy was necessary after chemotherapy in PMBL. Furthermore, historical evidence indicates that dose-intense regimens such as MACOP-B or VACOP-B (etoposide, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin) are superior to CHOP for PMBL, raising yet another question about the optimal chemotherapy for this disease.[20-22] Although the addition of rituximab to CHOP has improved the outcome for patients with DLBCL, there remains a high proportion of patients who do not achieve remission with R-CHOP, and in two recent studies, most of them received mediastinal radiation.[23,24] Recent results with the pharmacodynamically dose-adjusted regimen of doxorubicin, vincristine, and etoposide infused over 96 hours with bolus intravenous cyclophosphamide, rituximab and oral prednisone (DA-EPOCH-R) may be challenging the need for radiation in PMBL.[25-27] In a phase II study of DA-EPOCH-R in 40 patients with PMBL, 100% and 95% are alive and event free at a median 4-year follow-up, respectively, and only two patients required radiation treatment (see box on Treatment of Primary Mediastinal B-Cell Lymphoma).[27] These results suggest that DA-EPOCH-R obviates the need for radiation in almost all patients with PMBL, thus eliminating the risk of long-term toxicities such as secondary malignancies and heart disease. This is particularly important given that patients with PMBL are typically young and often women and are at increased risk of breast and other cancers as well as late-term toxicities.[28]

Systemic treatment is required for advanced stage DLBCL (Table 81-5). The CHOP regimen was developed some 30 years ago and was established as the standard by a randomized trial showing that CHOP was as effective as three other common albeit more complex or toxic regimens.[29] The fact that only 44% of patients achieved complete remissions (CRs) with CHOP, however, left significant room for improvement and spawned multiple studies aimed at improving treatment outcome.[29,30] Many of these studies focused on modifications to the CHOP platform. A GELA study compared doxorubicin; cyclophosphamide, vindesine, bleomycin, and prednisone (ACVBP) with CHOP in elderly patients with aggressive lymphoma and showed a superior 5-year event-free survival rate (EFS) of 39% and OS of 46% compared with 29% and 38% for CHOP, respectively.[31] Much of the benefit in the ACVBP arm, however, was due to a lower incidence of CNS progression, which could be attributed to the use of CNS prophylaxis with ACVBP. Furthermore, a previous study of ACVBP in low-IPI patients showed no benefit over m-BACOD, which was shown to be equivalent to CHOP.[32]

In aggressive lymphomas, high tumor proliferation determined by Ki-67 or MIB-1 immunohistochemistry has been shown to be an adverse prognostic finding with CHOP chemotherapy, suggesting that "kinetic" failure is a problem.[10,33] One strategy to overcome "kinetic" failure is to increase the dose density through frequent chemotherapy administration. The Deutsche Studiengruppe für Hochmaligne Non-Hodgkin Lymphome (DSHNHL) group evaluated the effect of dose density and etoposide in two four-arm studies of CHOP administered every 14 or 21 days with or without etoposide (CHOEP) in patients older than 60 years of age and low-risk patients 60 years of age or younger.[34,35] In the younger patients, CHOEP-21 demonstrated the best overall results with a CR rate of 88% versus 79% and EFS of 69% versus 58% at 5 years compared with standard CHOP-21, respectively.[35] In older patients, however, dose-dense CHOP-14 showed the best outcome with a CR rate of 76% versus 60% and EFS of 44% versus 33% at 5 years compared with standard CHOP-21.[34] Although these studies provided the best evidence that outcome could be improved through specific changes to the CHOP chemotherapy platform, it remains unclear why the optimal treatment differed in the studies given the continuum in disease biology across age.[10] The question of whether dose intensity can improve outcome has been and is being addressed in various other studies.[36,37]

An alternative strategy to dose density is to increase the fractional cell kill or efficacy of chemotherapy, thereby reducing the number of tumor cells that can survive and proliferate between cycles. Longer drug exposure may take advantage of the increased sensitivity of cycling cells, and in vitro studies have shown that prolonged low concentration exposure to vincristine and doxorubicin, compared with brief higher concentration exposure, can increase cytotoxicity by up to 1 log.[38] This approach was translated into the pharmacodynamically dose-adjusted DA-EPOCH regimen, which showed a promising progression-free survival (PFS) and OS of 70% and 73%, respectively, at 5-year median follow-up in newly diagnosed DLBCL.[25] Interestingly, high tumor proliferation was not found to be an adverse biomarker in this study.[25]

The development of rituximab has made the single greatest impact on the treatment of patients with DLBCL since CHOP was first introduced more than 30 years ago. The first study to show the benefit of rituximab was performed by GELA, in which patients older

Treatment of Primary Mediastinal B-Cell Lymphoma

Patients with a diagnosis of PMBL undergo routine CT staging of chest, abdomen, and pelvis. We administer 6 cycles of DA-EPOCH-R. After 4 cycles of therapy, we repeat CT staging, and after 6 cycles, we perform CTs and an FDG-PET scan. If patients have responded and the posttherapy PET scan result is negative, we repeat CT scans every few months. If the FDG-PET result is positive, we attempt to perform a biopsy, and if there is residual disease, patients undergo mediastinal radiation treatment. If the FDG-PET result is suspicious (low SUV values), we repeat it in 4 to 6 weeks. If at this time, the result becomes negative, patients go into routine follow-up, and if it remains abnormal, we perform a biopsy and administer radiation if the biopsy confirms residual disease.

Table 81-5 Treatment Regimens for Diffuse Large B-Cell Lymphoma

Study	Therapy	Patient group	Event-free Survival	Overall Survival	Reference
Phase III R-CHOP V CHOP	R-CHOP GELA	Age ≥60 yr All IPI	EFS: 47% at 5 yr	58% at 5 yr	[39,40]
Phase III R-CHOP V CHOP	R-CHOP U.S. Intergroup	Age ≥60 yr All IPI	FFS: 53% at 3 yr	NA	[42]
Phase III R-CHOP-like V CHOP	R-CHOP-like* MInT	Age ≤60 yr Low IPI	EFS: 79% at 3 yr	93% at 3 yr	[44]
Phase III ACVBP V CHOP	ACVBP GELA	Age ≥60 yr ≤1 IPI factor	EFS: 39% at 5 yr	46% at 5 yr	[31]
Single arm Phase II	DA-EPOCH-R NCI/CALGB	Age ≥18 yr All IPI	PFS: 81% at 62 mos	84% at 62 months	[49]
Phase III: four arms CHOP-14, CHOP-21, CHOEP-14, CHOEP-21	CHOEP-21 DSHNHL	Age 18–60 yr Good prognosis disease	EFS: 69.2% at 5 yr	NA	[35]
Phase III: four arms CHOP-14, CHOP-21, CHOEP-14, CHOEP-21	CHOP-14 DSHNHL	Age 61–75 yr All IPI	EFS: 43.8% at 5 yr	53.3% at 5 yr	[34]
Phase III: four arms R-CHOP-14 × 8, R-CHOP-14 × 6, R-CHOP-21 × 8, R-CHOP-21 × 6	R-CHOP-14 (X6) DSHNHL	Age ≥60 yr All IPI	EFS: 66% at 3 yr	78% at 3 yr	[43]
Phase III: two arms R-ACVBP V R-CHOP	R-ACVBP	Age 18–59 yr Only one adverse IPI prognostic factor	EFS: 81% at 3 yr	92% at 3 yr	[46]

ACVBP, Doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone; *CHOEP,* cyclophosphamide, doxorubicin, vincristine, etoposide, and prednisone; *DA-EPOCH-R,* dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin; *DSHNHL,* Deutsche Studiengruppe für Hochmaligne Non-Hodgkin'Lymphome; *GELA,* Groupe d'Etude Lymphomes d'Adultes; *IPI,* International Prognostic Index; *MACOP-B,* methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin; *MInT,* MabThera International Trial; *NCI,* National Cancer Institute; *PmitCEBO,* prednisone, mitozantrone, cyclophosphamide, etoposide, bleomycin, and vincristine; *R-CHOP,* rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone.
*CHOP-like regimens included CHOP, CHOEP, MACOP-B, and PmitCEBO.

than 60 years were randomized to receive CHOP or R-CHOP.[39] In this study, the CR (76% vs. 63%) and 5-year EFS (47% vs. 29%) were higher with R-CHOP than CHOP, respectively, making R-CHOP the "de facto" standard in DLBCL.[39,40] Recently, long-term follow-up of this study was presented, and the benefit of R-CHOP remains significant.[41] The benefit of rituximab has also been confirmed by the U.S. Intergroup study in a similar patient population.[42]

With the benefit of rituximab established, investigators have gone on to explore its use in a variety of clinical settings and treatment strategies. The DSHNHL group explored the question of whether there was a difference in outcome between 6 or 8 cycles of treatment in a randomized study of 6 versus 8 cycles of CHOP-14, with or without rituximab, in elderly patients with DLBCL. In that study, termed the RECOVER-60 trial, they found no difference in outcome with 6 versus 8 cycles of treatment.[43] Although they showed an excellent 3-year EFS of 66% with R-CHOP-14 over 6 cycles, which is somewhat better than the GELA and U.S. Intergroup study results, one cannot conclude that R-CHOP-14 is superior to standard R-CHOP-21, given all the caveats of inter-study comparisons. The MabThera International Trial (MInT) studied the benefit of rituximab with CHOP-based treatment in younger patients (60 years of age and younger) with favorable characteristics defined as low-IPI risk; furthermore, nearly half of patients received involved field radiotherapy.[44] Similar to the other randomized rituximab studies, patients who received rituximab fared significantly better with a 3-year EFS of 79%. As an interesting aside, the MInT study also showed that rituximab obviated the benefit of CHOEP in younger patients.[44] The additive role of rituximab in the context of dose intensity has also been evaluated, and in a recent update of the largest study that compared R-CHOP-14 with R-CHOP-21, there was no difference in overall survival between the two arms.[45] Recently, the GELA group compared R-CHOP-21 with R-ACVBP in younger patients (age 18–59 years) and at a median follow-up of 44 months demonstrated a significantly improved overall and PFS in patients who received R-ACVBP.[46]

Rituximab has also been tested in combination with the DA-EPOCH regimen.[47-49] In a recent report of 69 patients treated in a multicenter study, 81% and 84% of patients were progression free and alive, respectively, at the median follow-up of 62 months.[49] Furthermore, PFS was 87%, 92% and 54% for patients with low/low-intermediate, high-intermediate and high-IPI risk groups. PFS and EFS were 100% and 94%, respectively, for patients with germinal center tumors and 67% and 58%, respectively, for patients with

nongerminal center tumors. Evaluation of DA-EPOCH-R versus R-CHOP in untreated DLBCL is currently ongoing in the Cancer and Leukemia Group B (CALGB) cooperative group in conjunction with microarray analysis.

Although it is clear that rituximab has significantly improved the overall outcome of patients with DLBCL, several studies suggest its benefit is limited by tumor pathobiology.[50-52] Two studies found that rituximab benefit was primarily in Bcl-2 positive DLBCL, and another study showed that benefit was limited to Bcl-6 negative DLBCL.[50-52] These biomarkers are likely related to the new molecular taxonomy of DLBCL defined by gene profiling and suggest that rituximab may primarily benefit tumors derived from a nongerminal center B cell.[10,11,53] Recently, studies have suggested that molecular subtypes of DLBCL can be differentially targeted, and ongoing randomized studies are looking at the role of bortezomib when added to R-CHOP in nongerminal center DLBCL.[54,55]

Over the past few decades, there have been significant improvements in the outcome of patients with HIV-associated DLBCL, and these can be attributed to the widespread availability of combination antiretroviral therapy (CART) as well as advances in the therapeutics of these diseases.[56-58] Recently, the AIDS Malignancy Consortium in the United States reported excellent results with the DA-EPOCH-R regimen that were similar to survival outcomes in HIV-negative DLBCL.[59]

The role of high-dose chemotherapy and autologous stem cell transplantation (ASCT) in the initial treatment of patients with DLBCL remains controversial.[60,61] Although some studies have suggested benefit—recently, the GELA group reported promising results in high-risk DLBCL patients who received R-ACVBP followed by ASCT—this approach has not been compared with standard approaches.[62,63] ASCT is also associated with late toxicities, including leukemia and secondary myelodysplasia, which must be considered in the risk benefit of treatment.[64]

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Primary central nervous system lymphoma is a rare and highly aggressive lymphoma confined to the CNS and is usually of diffuse large B-cell histology. Its unique radiographic findings present challenges in evaluation, which have been recently addressed in a report of an international workshop to standardize criteria for baseline evaluation and response.[65] The incidence of PCNSL is particularly high in the setting of HIV infection, in which it often presents with multifocal disease and is virtually always associated with EBV. In contrast, PCNSL in HIV-negative patients often presents with solitary intracranial masses and is rarely associated with EBV (Fig. 81-4).

Treatment of PCNSL differs from systemic DLBCL because many chemotherapy agents do not adequately penetrate the blood–brain barrier. Radiotherapy has been a mainstay of treatment because it is effective and sidestepped the limitations of chemotherapy, but responses are usually short-lived, and virtually all patients relapse. High-dose methotrexate (HD-MTX), on the other hand, is a cytotoxic agent with good CNS penetration, but when used alone, PFS is a relatively short 7 months.[66] A logical step was to administer HD-MTX followed by whole-brain radiotherapy, and this resulted in an impressive 82% to 88% CR and median PFS rates of 32 to 40 months.[66-68] Unfortunately, such combined modality treatment is associated with severe long-term neurotoxicity.[66,69] For this reason, there has been much interest in developing regimens that obviate or defer the need for radiation until relapse. Most promising in this regard are combinations of HD-MTX with systemic agents that cross the blood–brain barrier, such as cytarabine, vincristine, and ifosfamide, particularly in patients younger than 60 years of age.[70] The Bonn group and others have adopted such an approach and have reported promising results with chemotherapy and deferred radiation in younger patients.[70,71] These results require further validation in trials. Studies are also addressing the role of immunochemotherapy with rituximab and other novel agents, which promise to further improve the outcome of patients with PCNSL.[72,73]

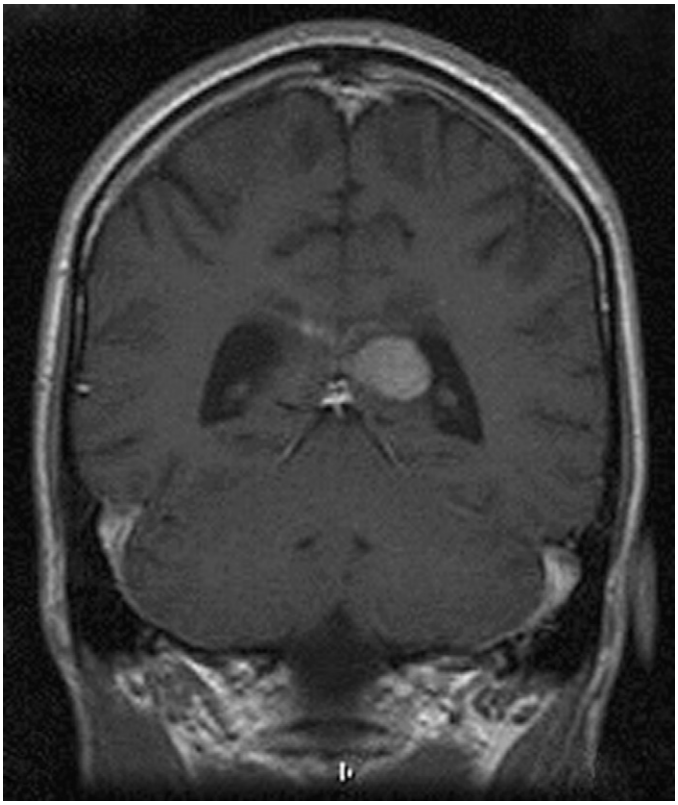

Figure 81-4 THIS GADOLINIUM-ENHANCED MAGNETIC RESONANCE IMAGING SCAN OF THE BRAIN SHOWS AN ENHANCING INFILTRATIVE MASS IN THE MAJOR FORCEPS OF THE CORPUS CALLOSUM. A biopsy was consistent with primary central nervous system lymphoma.

BURKITT LYMPHOMA

Epidemiology

Burkitt lymphoma mostly occurs in the first 2 decades of life, is more common in males, and accounts for some 2% of all lymphomas. There are three recognized clinical variants, and they vary in who they effect and how they present, and they also have morphologic and biological differences. Endemic BL occurs in equatorial Africa and Papua New Guinea, peaks in incidence in 4- to 7-year–old children, and is predominantly a male disease. Sporadic BL presents worldwide and is the most common variant in the Western world. It typically affects children and young adults and is more commonly observed in boys. Immunodeficiency-associated BL occurs in association with HIV infection and is approximately 1000 times more common in HIV-infected individuals.

Pathobiology

Burkitt lymphoma is highly aggressive and characterized by an extremely high proliferation fraction and a high fraction of apoptosis, and this accounts for its "starry sky" appearance. Although a leukemic phase of BL can occur in patients with advanced disease, it is very rare for BL to present purely as acute leukemia. Biologically, BL is derived from a germinal center B cell as indicated by its CD20+, CD10+, and TdT-negative immunohistochemical profile and gene expression profiling.[74] The neoplastic cells are usually negative or weakly positive for BCL2. Although EBV is virtually always detected in endemic BL, it is only present in 25% to 40% of sporadic and immunodeficiency-associated cases.

Although virtually all cases of BL have MYC translocations, usually at 8q24 to the IG heavy chain region, MYC translocations

are not specific for BL and can be found in other aggressive B-cell lymphomas (Fig. 81-5). BL has a unique gene expression signature that is molecularly distinct from that of DLBCL. Studies have demonstrated that some cases of DLBCL by histology have gene expression profiles consistent with BL.[74-76] Given that BL does not respond well to CHOP-based treatments, this distinction by molecular profiling is important, and gene expression profiling may be useful in rare cases that would otherwise be diagnosed as DLBCL. Additionally, there are cases with a profile intermediate between that of DLBCL and BL; these cases typically harbor MYC and have a poor outcome with CHOP-based regimens.

Clinical Features

The clinical presentation of BL is variable and depends on the epidemiological subtype as well as other factors. In endemic BL, it is common for patients to present with jaw and other facial disease, and other extranodal sites of involvement include the ileocecum, gonads, kidneys, and breasts. The ileocecal area is the most common site of disease involvement in sporadic BL (Fig. 81-6), and jaw involvement is very rare. In immunodeficiency-associated BL, involvement of the ileocecum, LNs, and BM is commonly observed. Patients often present with advanced stage and bulky disease caused by the short doubling time of the tumor, and it is common for patients to develop tumor lysis syndrome (TLS) after the institution of therapy.

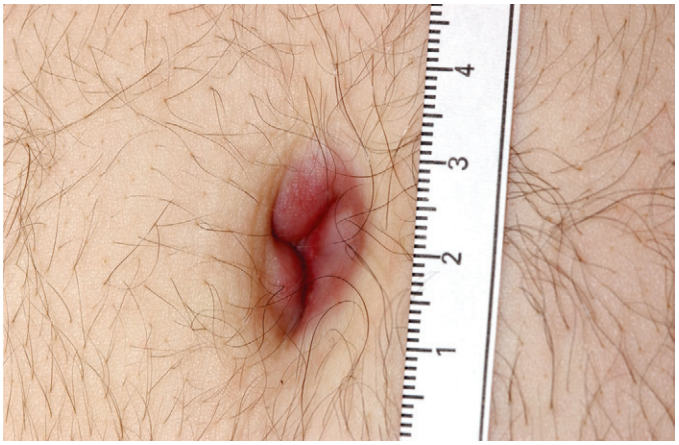

Figure 81-5 BURKITT LYMPHOMA (BL) INVOLVING THE UMBILICUS. This is an 18-year old man who presented with a history of abdominal pain. Computed tomography scan demonstrated a large intraabdominal mass extending up to the umbilicus, and a biopsy revealed it to be BL.

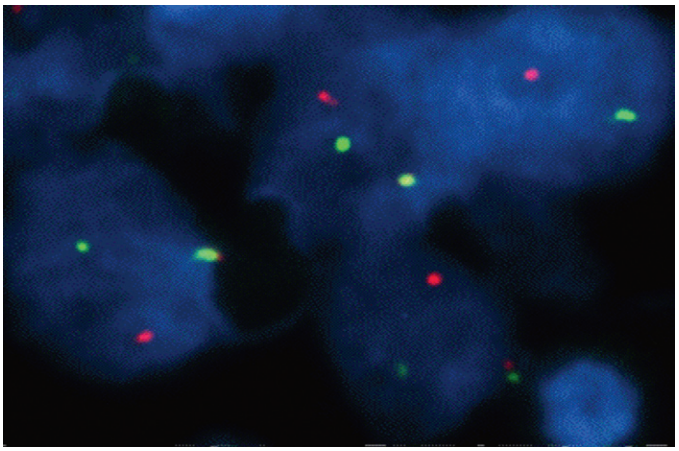

Figure 81-6 FLUORESCENT IN SITU HYBRIDIZATION SHOWING AN MYC TRANSLOCATION IN A PATIENT WITH DIFFUSE LARGE B-CELL LYMPHOMA.

Investigation

History and Physical Examination and Laboratory Investigations

Similar to patients with DLBCL, a detailed history and physical examination is required, and the diagnosis of BL should be made by an experienced hematopathologist. Given its association with HIV infection, it is imperative to perform an HIV test at diagnosis and to check hepatitis serologies.

Imaging and Staging

As with DLBCL, imaging studies should include chest radiography and CT scanning of the chest, abdomen, and pelvis. The need for additional imaging studies depends on the clinical presentation. A BM aspirate and biopsy should be performed in all patients, and all patients should undergo lumbar puncture with evaluation of the CSF by cytology and flow cytometry.[4] Although BL in adults is staged according to the Ann Arbor staging system, the Murphy staging system is often used in children.

Prognosis

Age, large tumor volume, and CNS involvement have been associated with a poor prognosis in the past. Although early studies demonstrated that HIV-positive patients with BL had a worse outcome, this has not been the case with newer treatment approaches.

Treatment

Burkitt lymphoma is a systemic disease and requires chemotherapy for all disease stages. Importantly, locoregional radiation does not improve survival and should be avoided. Although older studies demonstrated that surgical resection of abdominal disease improved outcome, indicating the importance of tumor volume, more effective and risk-adapted treatments have made surgical resection unnecessary except for specific complications such as obstruction, perforation, fistula, or bleeding.

Early treatment strategies for BL were modeled on acute lymphoblastic leukemia (ALL) regimens that used dose-intense and prolonged treatment with induction, consolidation, and maintenance phases. These approaches stand in contrast to the significantly less dose-intense regimens used in adults with "intermediate-grade" lymphoma, such as CHOP and CHOP-based regimens, that only produced a 50% to 60% EFS. Although dose intensity and dose density are important treatment components for BL, later studies indicated that shorter treatment durations were equally effective. Furthermore, the recognition that tumor volume is an important prognostic feature led to the use of risk adaptive approaches and a further reduction in treatment for patients with early stage disease. Several biological characteristics of BL have helped guide treatment strategies, including its high proliferative fraction. It has been recognized for years that BL is sensitive to multiple chemotherapy classes, and in endemic BL, cures were occasionally achieved with single-agent cyclophosphamide. Despite initial sensitivity, however, patients frequently relapsed, particularly those with higher volume disease. This apparent dichotomy can potentially be explained by the high tumor proliferation rate, resulting in "kinetic" failure. One strategy to overcome "kinetic" failure is to increase the dose density through frequent chemotherapy administration, a strategy used in most current BL regimens. Another strategy is to increase the fractional cell kill or efficacy of chemotherapy, thereby reducing the

number of tumor cells that can survive and proliferate between cycles. Hence, BL regimens commonly use multiple chemotherapy agents in high doses and alternating cycles. They typically include anthracylines, epipodophyllotoxins, vinca alkaloids, and alkylators, as well as methotrexate and cytarabine, which are cell cycle active agents and take advantage of the high tumor proliferation. These agents, however, are administered in a variety of combinations and schedule, indicating the empiric nature of the actual combinations.

The risks of TLS and propensity for CNS dissemination in BL also have important treatment implications. All patients should receive TLS prophylaxis during the first cycle and undergo close monitoring of their electrolytes. The high risk of CNS involvement has prompted the use in the past of relatively high-dose intravenous methotrexate and cytarabine—both of which have CNS penetration—and intrathecal administration of these drugs. An important advance has been to reduce intrathecal treatment and eliminate whole-brain radiation for prophylaxis, which has significantly reduced CNS toxicity. A recently published FAB/LMB study demonstrated that patients with early stage BL had a high cure rate and very low rate of CNS relapse without the use of intrathecal chemotherapy.[77]

There are multiple highly effective regimens for BL; however, because of the rarity of the disease—there are only 1200 new cases in the United States each year—there are no good comparative studies of different therapies in BL. A variety of dose-intense short-duration regimens have achieved durable CRs in 47% to 84% of patients.[78-81] Included in these are the French LMB and German Berlin-Frankfurt-Munster (BFM) protocols and the National Cancer Institute CODOX-M/IVAC (cyclophosphamide, vincristine, doxorubicin, and HD-MTX alternating with ifosfamide, etoposide, and high-dose cytarabine; intrathecal methotrexate and cytarabine are also administered) regimen. These regimens are similar in their drug composition, short cycle length, and CNS prophylaxis. Although most BL occurs in children, Magrath and colleagues[82] demonstrated that adults have a similar disease outcome when treated with the same regimen and reported cure rates approaching 90%. Other groups have confirmed the efficacy of this regimen albeit with lower survival rates. In the United Kingdom, Mead et al[83] reported an overall EFS of 65% at 2 years. The hyper-CVAD regimen has also been tested in BL with good results (recently with the addition of rituximab).

Toxicity is an important clinical limitation of these regimens in adults, particularly in older patients and in patients who are immunosuppressed, in whom severe morbidity and even mortality occur. Therefore, one of the major therapeutic challenges in BL is to develop therapies that are as effective in achieving high cure rates as "standard" regimens but that also improve the therapeutic index and reduce toxicity complications. This approach has been investigated in a study using DA-EPOCH-R in BL. Based on the efficacy of the regimen in a DLBCL study—which suggested that DA-EPOCH overcomes the adverse effect of high proliferation, likely because of its infusional schedule—a study was undertaken in BL. A recent update reported an EFS of 97% in 29 patients at a median follow-up time of 57 months.[84] There were very low rates of TLS and other toxicities compared with conventional BL regimens. Many different approaches have been tested in patients who have HIV-associated BL. As with older patients, treatment-related toxicity can be an important consideration in this population, and regimens such as DA-EPOCH-R are well tolerated and effective.[84]

SALVAGE THERAPY

The salvage treatment of relapsed DLBCL should be approached in an individual manner because the choice of treatment is influenced by the time to recurrence, prior therapy, medical condition, and the potential for cure. Although most relapsed aggressive lymphomas require combination chemotherapy for adequate disease control, it is important to recognize that patients with local disease may be salvaged with radiation therapy. Examples include primary mediastinal DLBCL, which can remain local even at relapse, and PTLDs, which may have an isolated resistant EBV clone after chemotherapy.[85]

A variety of active salvage chemotherapy regimens are available for relapsed or refractory DLBCL.[86-92] Platinum-containing regimens, such as ESHAP (etoposide, methylprednisolone, cytosine arabinoside, and platinum) and ICE, are currently among the most widely used salvage treatment.[88,90,93] It is a commonly held notion that salvage treatment should include different agents from past treatment to avoid drug resistance. Recent evidence indicates, however, that sensitivity to apoptosis is a central cause of drug resistance and that drug-specific mechanisms are less important.[10,94] Hence, salvage regimens developed around the most active upfront agents should show high activity.[95] The addition of rituximab appears to enhance the activity of salvage regimens as demonstrated by results with R-ICE (rituximab, ifosfamid, carboplatin, and etoposide) and ICE (ifosfamid, carboplatin, and etoposide), which showed CRs of 53% and 27%, respectively.[88,93]

Patients with chemotherapy-sensitive disease have the best outcome with ASCT, and this is recommended at initial relapse; in the pre-rituximab era, this approach yielded OS and EFS rates in the range of 40% to 50% and 30% to 40%, respectively.[88,96] However, the improvement in upfront curability of DLBCL because of immunochemotherapy has diminished the efficacy of ASCT at relapse, which was recently demonstrated in the CORAL study, in which the 3-year EFS of patients who had initially received rituximab was merely 21% after ASCT.[97] Of course, patients with chemotherapy-resistant disease do poorly with ASCT and should be considered for experimental treatments such as allogeneic SCT.

The outcome for patients with BL who relapse after or progress during initial therapy is extremely poor, and there are no standard approaches that have been associated with good outcomes; therefore, experimental approaches such as allogeneic SCT (if it is feasible) should be considered.

Late Complications of Treatment and Follow-up

It is important to recognize that successful treatment may be associated with late complications that may not appear for decades. Among the major late-term complications are secondary malignancies, ischemic heart disease, anthracycline-related cardiotoxicity, and radiation- or bleomycin-induced pulmonary toxicity.[98] The risk of developing myelodysplastic disorders and acute myeloid leukemia is related to alkylator and topoisomerase inhibitor use and is enhanced by radiation. Radiation therapy increases the risk of malignancy in the treatment region, particularly breast cancer in women and lung cancer in smokers. Indeed, it is imperative to consider late-term toxicity when selecting treatment.

A general guideline for follow-up after initial therapy involves visits every 3 months for 2 years, every 6 months for 3 years, and annually thereafter. During these visits, examination of the LN areas, abdomen, thyroid, and skin is important. CT scans are recommended in routine follow-up. It is important to note that CT scans are associated with a relatively high radiation exposure and projected risks and should not be used unnecessarily.[99] PET scans are not recommended for routine follow-up because the high rate of false-positive scans is unlikely to offset the value of early detection. Indeed, the role of PET scans in the overall treatment of lymphomas needs to be prospectively studied.[100] Routine laboratory studies with blood counts, liver function tests, and LD should be performed. Patients with disease in the chest area can be followed with chest radiographs. Thyroid-stimulating hormone levels should be monitored annually in patients who received neck radiotherapy. Mammography for women should begin 10 years from the diagnosis of lymphoma or at age 40 years, whichever comes first.

FUTURE DIRECTIONS

Over recent years, we have made significant advances in elucidating the molecular biology of DLBCL and BL, and this has led to an era of enhanced and exciting drug discovery. In DLBCL in particular,

many critical pathways and novel targets have been identified, and many small molecule inhibitors are being investigated and in development as a result of these advances. For example, in the ABC subtype of DLBCL, constitutive activation of nuclear factor kappa B (NF-κB) has been shown to be an important inhibitor of apoptosis, and this may lead to chemotherapy resistance. Therefore, bortezomib, an inhibitor of NF-κB, was tested in DLBCL, and outcomes according to molecular subtype suggested that it enhances the activity of chemotherapy in ABC but not GCB DLBCL.[54,55] Recent work has identified that chronic active B-cell receptor signaling is an important mechanism of ABC tumor cell survival; to test this clinically, studies in patients with ABC DLBCL are in progress targeting specific components of this pathway (Bruton tyrosine kinase [BTK] by PCI-32765).[101-104] In BL, cure rates are very high with conventional approaches, and the challenge for the future is to further develop strategies that maintain the efficacy of "standard" treatment but with much less toxicity. To advance the therapeutics of these diseases, it is critical to wisely choose which drugs should be developed and incorporated into upfront clinical trials and to pair drug development with understanding of tumor biology.

CHAPTER 82

VIRUS-ASSOCIATED LYMPHOMA

Jennifer A. Kanakry and Richard F. Ambinder

There are five well-characterized human viruses that are generally accepted as important in lymphomagenesis (Table 82-1). These viruses may infect tumor cells (or their progenitors) or may act at a distance. The genomes of Epstein-Barr virus (EBV), Kaposi sarcoma–associated herpesvirus (KSHV, also known as *human herpesvirus 8* [HHV-8]), and human T-lymphotropic virus-1 (HTLV-1) are present in tumor cells. The viral genes expressed in tumor cells modulate cellular metabolism, proliferation, and cell death. In contrast, the human immunodeficiency virus (HIV) genome is generally not detected in tumor cells. Whether hepatitis C virus (HCV) genomes are present in lymphoma cells remains a subject of controversy.

Although viral infection plays a role in the pathogenesis of some lymphomas, lymphomagenesis is unusual. Only a small subset of infected people develops lymphoma. Furthermore, although primary viral infection may be followed by lymphomagenesis within days or weeks in exceptional circumstances, most lymphomas arise years or decades after primary infection. Indeed the term *adult* in adult T-cell leukemia/lymphoma (ATL) reflects the time lag between HTLV-1 infection in infancy and the evolution to malignancy. Geography and associated environmental exposures, host genetic factors, and immune status all modify risk.

Aspects of the biology and epidemiology of each of these viruses and their relationship with lymphomagenesis are reviewed. In addition, clinically important and distinctive features of diagnosis and treatment of the associated lymphomas are presented.

EPSTEIN-BARR VIRUS

Viral Biology

EBV is a gammaherpesvirus transmitted mainly through saliva.[1,2] After primary infection, some of the infected cells are driven to proliferate and thereby spread infection throughout the B-cell compartment. Ultimately, in the normal host, there is an immune response that controls infection and eradicates virus-infected proliferating cells. Thereafter the viral genome is harbored mainly in resting memory B lymphocytes that persist for life. These B cells that harbor virus elude immune surveillance in part because of their very restricted viral gene expression such that few viral antigens are presented. Occasionally there is activation of viral lytic gene expression (at least in some instances this occurs in concert with plasma cell differentiation) leading to production of infectious virions that may infect other B cells. T cell–mediated immune function keeps such proliferation in check.[3]

In vitro EBV immortalizes B cells such that they grow indefinitely as lymphoblastoid cell lines (LCLs) (Fig. 82-1). LCLs are tumorigenic in immunodeficient mice. In LCL, viral genomes are present as circular double-stranded deoxyribonucleic acid (DNA) episomes within the nucleus. The viral proteins required for immortalization include Epstein-Barr virus nuclear antigen-1 (EBNA1), a sequence-specific DNA-binding protein important in the maintenance of the viral episome; EBNA2, a transcription factor that has many effects similar to those of activated Notch receptors; and latent membrane protein-1 (LMP1), a constitutively activated member of the tumor necrosis factor (TNF) receptor superfamily, which most closely resembles CD40.[4] LMP1 activates the nuclear factor kappa-B (NFκB) pathway, which modulates cell proliferation and apoptosis.[5] Several other EBV proteins are also required for immortalization. Although EBV immortalization of B cells in vitro may offer some insights into tumorigenesis, some caution is required in using LCL as a tumor model. Most EBV tumors, including tumors of B-lineage cells, do not express many of the viral genes required for lymphocyte immortalization. The only tumors that express the full complement of viral proteins required for immortalization are those that arise in the most profoundly immunocompromised patients (organ or hematopoietic transplant recipients, patients with congenital immunodeficiency, or patients with far advanced acquired immunodeficiency syndrome [AIDS]). Thus in posttransplantation lymphoproliferative disorder (PTLD), tumor cells may resemble LCL in expressing many viral latency genes in association with normal karyotype (and few mutations of the cellular genome). It has been suggested that there is an inverse relationship between cellular mutations and viral gene expression in tumors.[6]

EBV gene expression may directly drive proliferation or inhibit apoptotic pathways as illustrated by lymphocyte immortalization. However, viral gene expression may also perturb normal lymphocyte biology. Thus LMP1 expression upregulates activation induced (cytidine) deaminase expression, which facilitates somatic hypermutation and immunoglobulin class switching.[7] LMP1 expression may also be important in the conversion of naive B-cells to post-germinal center memory B-cells. LMP2A allows B-cells that lack normal immunoglobulin expression to escape regulatory checkpoints and survive.[8]

Epidemiology of Viral Infection

EBV infection is ubiquitous. The vast majority of adults are infected worldwide. Primary infection is most often asymptomatic, especially when it occurs in childhood.[9] Primary infection may be associated with the syndrome of infectious mononucleosis. Symptomatic primary infection occurs more frequently in older children and in adults than in younger children. Other possible determinants of symptomatic primary infection include genetic factors and possibly the size of the viral inoculum.

Strain differences in EBV are well recognized.[10] However, the importance of these strain differences with regard to lymphomagenesis remains poorly understood. There is general agreement that the Type 1 strain EBV is most common worldwide and in tumors. The Type 2 strain virus has been identified in some African Burkitt lymphoma (BL) and in some AIDS-associated lymphoma. A-strain virus is more efficient at lymphocyte immortalization in vitro and lymphomagenesis in mouse models. The two strains of virus differ mainly in the EBNA2 gene, but differences are recognized in some other viral proteins as well.[11] Variations in the regulatory regions or coding regions of a variety of other genes including EBNA1, LMP1, and ZTA have been recognized and suggested to play a role in lymphomagenesis.

A simple classification of latent viral gene expression recognizes three patterns as shown in the Table 82-2.

Table 82-1 Viruses and Lymphomagenesis

Virus	Viral Genome in Tumor Cell	Lymphoma Type
EBV	Episomal	B, T, NK
KSHV	Episomal	B
HTLV-1	Integrated	T
HIV-1	Absent	B
HCV	Uncertain	B

EBV, Epstein-Barr virus; *HCV,* hepatitis C virus; *HIV-1,* human immunodeficiency virus type 1; *HTLV-1,* human T-lymphotropic virus-1; *KSHV,* Kaposi sarcoma–associated herpesvirus; NK, natural killer.

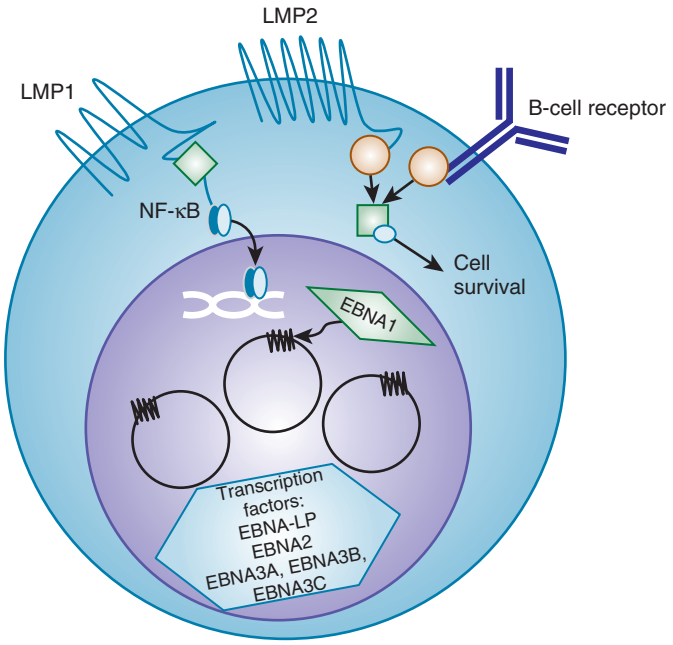

Figure 82-1 EPSTEIN-BARR VIRUS (EBV)–IMMORTALIZED B CELL. Normal B cells are readily immortalized in vitro with EBV. These cells express EBV nuclear and membrane proteins. The nuclear proteins include a protein expressed in all EBV-associated tumors, Epstein-Barr virus nuclear antigen 1 (EBNA1). This protein is required for episomal maintenance. Other viral nuclear proteins expressed are transcription factors. These include EBNA-LP, EBNA2, EBNA3A, EBNA3B, and EBNA3C. Two membrane proteins are expressed: latent membrane protein 1 (LMP1), which activates NFκB pathways, and LMP2A, which mimics B-cell receptor (immunoglobulin) signaling.

Epstein-Barr Virus Detection in Clinical Specimens

The sensitivity of polymerase chain reaction (PCR) makes detection of viral DNA straightforward, but the ubiquity of EBV infection, and the persistence of B cells that harbor EBV in all seropositive individuals, means that EBV DNA is readily detected in many specimens that include normal lymphocytes. Thus diagnosis of the EBV association in general requires viral detection specifically in tumor cells. Techniques for viral DNA detection by fluorescence in situ hybridization or related techniques, although greatly improved in recent years, remain the purview of research laboratories and are generally not readily applicable to clinical specimens. This reflects the relatively low copy number of the viral genome in tumor cells, typically 1 to 200 copies per cell. In contrast, in situ hybridization for the Epstein-Barr encoded ribonucleic acids (RNAs) has emerged as a laboratory standard.[12] These RNAs are polymerase 3 transcripts that are expressed

Table 82-2 Patterns of Epstein-Barr Virus Gene Expression in Latency

Latency	EBNA1	EBNA2, EBNA3A, EBNA3B, EBNA3C	LMP1	LMP2A
I	+			
II	+		+	+
III	+	+	+	+

EBNA1, Epstein-Barr virus nuclear antigen 1; *EBV,* Epstein-Barr virus; *LMP1,* latent membrane protein 1.

at very high copy number (perhaps millions of copies per cell) in latently infected cells. The function(s) of these RNAs is disputed, but their use for the detection of virus in a variety of surgical specimens is generally accepted.

Viral antigens are detected by immunohistochemistry. In clinical laboratories, immunohistochemistry for LMP1 is commonly employed and is sensitive for the detection of EBV in Hodgkin lymphoma (HL). In a variety of other EBV-associated B- and T-cell malignancies, expression is variable. Thus failure to detect LMP1 expression does not exclude the presence of EBV except perhaps in HL. In principle, detection of EBNA1 should be universally applicable, although the low level of antigen expression and the cross-reactivity of available monoclonal antibodies have prevented immunohistochemistry for this antigen from emerging as a standard tool.

Association With Particular Types of Lymphoma

Some lymphoma types are nearly 100% EBV associated, including endemic BL, extranodal natural killer (NK)/T-cell lymphoma of the nasal type, early PTLD, lymphomatoid granulomatosis, diffuse large B-cell lymphoma (DLBCL) associated with chronic inflammation, EBV-positive DLBCL of older adults, and AIDS primary central nervous system (CNS) lymphoma (PCNSL).[13-16] Other lymphoma types are variably EBV associated. These include classic HL, PTLDs occurring many months or years after transplantation, and systemic AIDS-related lymphoma. Some lymphoma types appear never or almost never to be EBV associated, including follicular lymphoma, nodular lymphocyte-predominant HL, and mantle cell lymphoma. Table 82-3 lists the lymphomas that have been associated with EBV, associated cofactors, viral antigen expression, and an estimate of the percentage of tumors within each lymphoma subtype that harbor viral genomes.

Posttransplantation Lymphoproliferative Disorder

PTLD is a group of lymphoproliferative disorders ranging from polyclonal lymphoid hyperplasia to lymphomas that arise in patients after solid organ or hematopoietic stem cell transplantation (HSCT).[17] PTLD, especially in the first few months after transplantation, is highly associated with EBV (Fig. 82-2, *A, B*). EBV gene expression in PTLD corresponds to latencies 2 and 3.[18] Broad expression of viral proteins is seen only in immunosuppressed hosts, perhaps reflecting that many of these proteins are commonly targeted by cytotoxic T cells.

B cells that harbor EBV are able to proliferate in the setting of posttransplantation immunosuppression at least in part due to decreased T-cell surveillance.[19] HSCT patients that receive grafts that have been T-cell depleted develop EBV-associated PTLD at very high rates. Treatment of rejection in solid organ transplant recipients with agents such as the monoclonal antibody OKT3, which targets $CD3^+$ cells, is associated with markedly increased risk for PTLD.[20] Treatment strategies such as the use of rituximab and infusion of EBV-specific cytotoxic T cells have been quite effective in treating or preventing PTLD (see box on Epstein-Barr Virus-Associated Positive Posttransplant Lymphoproliferative Disorder).

Table 82-3 Epstein-Barr Virus-Associated Lymphoma

Type	Cofactors	Viral Gene Expression	Approximate % EBV Associated	Comment
PTLD	Immunosuppression, allograft	Latency II or III	50-95	Early days/months after transplantation are more commonly associated with EBV
Sporadic BL		Latency I	20 in the United States	Higher in Latin America
Endemic BL	Malaria	Latency I	>95	
AIDS BL	HIV	Latency I	30	
HL		Latency II	30 in the United States	Higher % in mixed cellularity, in males, in Hispanics
AIDS PCNSL	HIV	Latency II or III	>95	
Nasal-type NK cell	More common in Asia	Latency II	>95	
AIDS PEL	HIV and KSHV	Latency I	>75	

AIDS, Acquired immunodeficiency syndrome; *BL,* Burkitt lymphoma; *EBV,* Epstein-Barr virus; *HIV,* human immunodeficiency virus; *HL,* Hodgkin lymphoma; *KSHV,* Kaposi sarcoma–associated herpesvirus; *NK,* natural killer; *PCNSL,* primary central nervous system lymphoma; *PEL,* primary effusion lymphoma; *PTLD,* posttransplantation lymphoproliferative disorder.

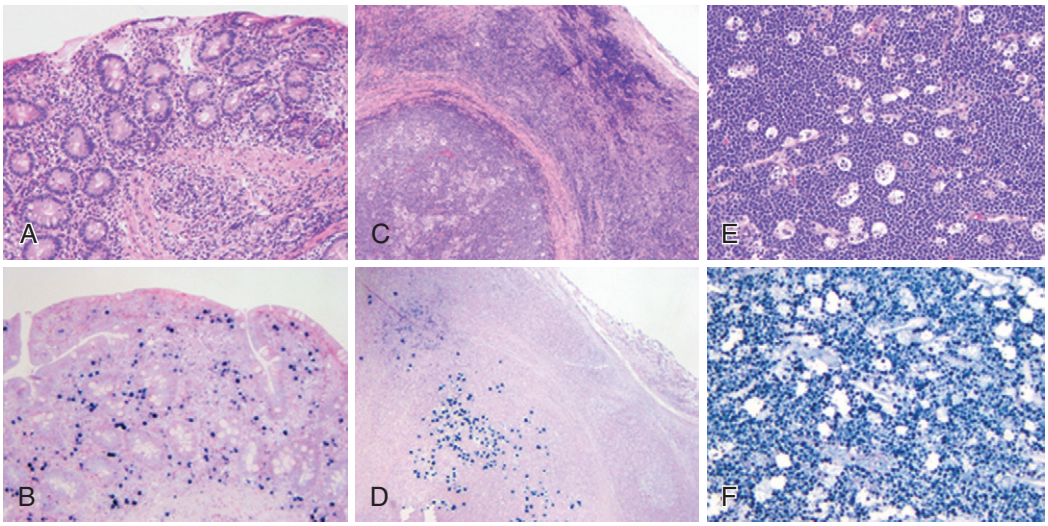

Figure 82-2 EXAMPLES OF EPSTEIN-BARR VIRUS (EBV)–RELATED LYMPHOMAS. Posttransplantation lymphoproliferative disorder (PTLD), polymorphic type, EBV+ occurring in the gastrointestinal tract of a 15-month-old girl following an orthotopic liver transplant (**A** and **B**). There was a mildly atypical lymphocytic infiltrate in the duodenal mucosa composed of small lymphocytes, plasma cells, and occasional large cells (**A**). The infiltrate was EBV+ as demonstrated by in situ hybridization for Epstein-Barr–encoded RNA (EBER) (**B**). Hodgkin lymphoma, nodular sclerosing type, EBV+ (**C** and **D**). The hematoxylin-eosin section shows a portion of a lymph node from a cervical lymph node biopsy of an 8-year-old girl. There are bands of sclerosis forming a cellular nodule, and within the nodule there is a mixed inflammatory infiltrate and scattered large cells with contracted cytoplasm consistent with lacunar cells (**C**). The immunophenotype of these cells was that of classic Hodgkin lymphoma, and the cells were EBER+ (**D**). EBV is seen more frequently in mixed cellularity Hodgkin lymphoma but can be seen in 10% to 40% of cases of nodular sclerosing type. It is even more frequent in cases associated with human immunodeficiency virus (HIV; see text) and in resource-poor regions. Burkitt lymphoma, sporadic type, EBV+ (**E** and **F**). A section of the cervical lymph node biopsy of a 9-year-old girl with a rapidly enlarging neck mass is shown. The section illustrates the classic morphologic features of Burkitt lymphoma with a "starry sky" appearance, sheets of intermediate-sized cells with multiple small nucleoli and high mitotic rate. The cells were virtually all EBER+ (**F**). EBV can be seen in about 20% to 30% of cases of sporadic Burkitt lymphoma and is essentially always positive in endemic cases.

Hodgkin Lymphoma

Approximately 30% of HL tumors in the United States and Europe are EBV associated (Fig. 82-2, *C, D*).[21,22] Epidemiologic studies in Denmark and Sweden suggest that individuals with a history of symptomatic infectious mononucleosis are at increased risk for EBV-associated HL, but not for EBV-negative HL or other lymphomas.[23] The period of risk peaks at about 2 years but continues to be elevated for at least 10 years after symptomatic mononucleosis.

Higher EBV associations are seen in Latin America, Africa, and parts of Asia. Factors associated with EBV tumor positivity include mixed cellularity and lymphocyte-depleted classic HL histologic subtypes, male gender, low socioeconomic background, history of symptomatic infectious mononucleosis, and Hispanic ethnicity.[21,24,25] Organ and hematopoietic stem cell transplant recipients and HIV-positive patients are more likely to develop HL than the general population, and approximately 90% of the tumors are EBV associated.[26]

The EBV gene expression pattern in HL is latency II even when HL occurs in immunocompromised populations.[27] LMP1 and LMP2A may mimic signaling of B-cell receptors and thus protect B cells lacking functional immunoglobulin expression from apoptotic signaling. Approximately 20% of HL lack productive immunoglobulin gene rearrangements. These tumors appear to be exclusively EBV associated.

The EBV association of HL appears not to have prognostic import in young adult patients but is associated with poorer survival in older patients in several reports.[22] Treatment strategies involving adoptive therapy with EBV-specific T cells expanded in vitro are under study.[28]

Burkitt Lymphoma

Endemic BL is nearly 100% associated with EBV, whereas sporadic and HIV-associated BL are much more variably EBV associated (see Table 82-3 and Fig. 82-2, *E, F*).[29] Viral expression is latency I (i.e., EBNA1 is the only viral protein consistently expressed). The defining feature of BL is a translocation between c-Myc on chromosome 8 and one of the immunoglobulin genes on chromosomes 2, 14, or 22. It has been generally presumed that falciparum malaria is a cofactor in endemic BL, and the distribution of BL in Africa corresponds to the distribution of holoendemic malaria. However, little is understood of the pathogenesis or interaction between these infectious cofactors. The characteristic presentation of BL is different in the endemic versus sporadic settings, but there is no evidence to link these presentations specifically with the virus. The virus-tumor association does not guide diagnosis, therapy, or estimation of prognosis at present.

Epstein-Barr Virus-Associated Positive Posttransplant Lymphoproliferative Disorder

A 55-year-old renal transplant patient presents with acute renal failure 5 months after transplant. She is found on imaging to have an obstructing mass in the transplanted kidney. She undergoes kidney biopsy, and Epstein-Barr virus (EBV)–positive posttransplant lymphoproliferative disorder (PTLD) involving the transplanted organ is diagnosed. Treatment options include rituximab; decreasing immunosuppression (acknowledging the associated risk for organ rejection); changing immunosuppressive agents—switching a calcineurin inhibitor for a mammalian target of rapamycin (mTOR) inhibitor; combination chemotherapy; or, in the case of renal transplant, removal of the transplanted organ and withdrawal of immunosuppression.

Diffuse Large B-cell Lymphoma Associated With Chronic Inflammation

EBV-associated lymphomas sometimes arise in the setting of long-standing chronic inflammation.[15] This was first described in Japanese patients with a remote history of pulmonary tuberculosis treated with thoracoplasty with resulting chronic pyothorax, although many more cases have since been reported. These patients developed EBV-associated DLBCL of the pleural lining and associated lung tissue decades after thoracoplasty. Similar cases of aggressive, EBV-associated B-cell lymphomas have been reported to arise in patients at the sites of chronic inflammation associated with various implants, surgical mesh, or in the lung after chronic empyema.

KAPOSI SARCOMA–ASSOCIATED HERPESVIRUS

Virus and Tumor Epidemiology

KSHV (HHV-8) is a gammaherpesvirus that, unlike EBV, has a low prevalence worldwide.[30] The virus is endemic in certain areas, such as in sub-Saharan Africa and the Middle East, and has an intermediate prevalence in Mediterranean countries. Transmission is believed to be predominately through saliva. Similar to EBV, KSHV latently infects B cells; viral genes that promote cell survival are implicated in lymphomagenesis.

KSHV was discovered in Kaposi sarcoma but is also present in two lymphoproliferative diseases: primary effusion lymphoma (PEL) (Fig. 82-3, *A, B*) and multicentric Castleman disease (MCD).[16,31] PEL occurs almost exclusively in HIV-positive patients, particularly in men who have sex with men, and typically when CD4 counts are less than 100/mm^3. PELs are usually dually infected with KSHV and EBV, but KSHV is always present. KSHV-associated MCD, although much more common in HIV-infected populations, also occurs in the general population.

MCD is a KSHV-associated, immunoglobulin M (IgM) λ–producing nonclonal lymphoproliferative disorder typically involving the mantle zone of lymph nodes and the spleen. The KSHV-positive cells in MCD are always EBV negative. These cells express a broad range of KSHV lytic antigens, and high KSHV copy numbers are reported in plasma. Evolution into or coassociation with an aggressive lymphoma, often of plasmablastic phenotype, is not uncommon.

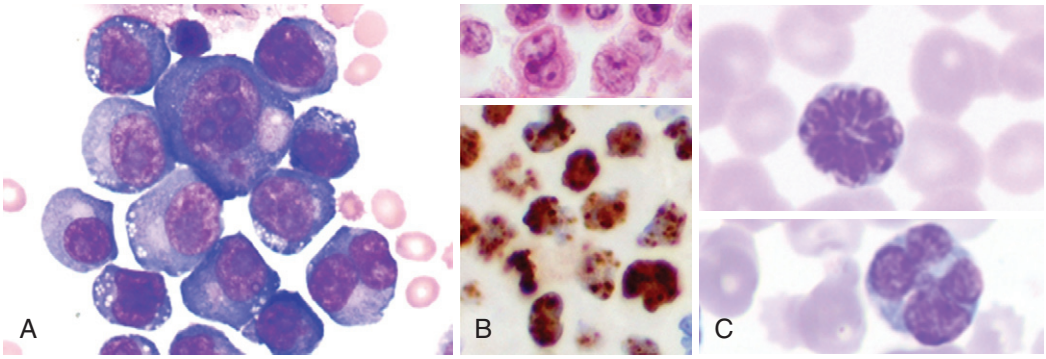

Figure 82-3 EXAMPLES OF KSHV- AND HTLV-1-ASSOCIATED LYMPHOPROLIFERATIVE DISEASE. Primary effusion lymphoma (**A** and **B**). **A,** The pleural tap had a high cell count, and the cytospin preparation revealed a markedly pleomorphic cell population with large and giant cells with deep-blue cytoplasm. **B,** A cell block was prepared *(top)* so that in situ hybridization studies could be performed. These studies showed the cells to be KSHV+ by immunohistochemistry for latency associated nuclear antigen-1 (LANA-1) *(bottom)* and EBV+ by EBER in situ hybridization (not shown). **C,** Adult T-cell leukemia/lymphoma in a patient who was HTLV-1+. The peripheral smear showed the classic "flower" cells. *EBER,* Epstein-Barr–encoded RNA; *HTLV-1,* human T-lymphotropic virus-1; *KSHV,* Kaposi sarcoma–associated herpesvirus. *(***A** *and* **B** *courtesy Dr. Elizabeth Hyjek, University of Chicago.)*

Within the HIV population, nearly all cases of MCD are KSHV associated; this viral association is not as strong among HIV-negative MCD patients. High expression of viral interleukin-6 (vIL-6) is thought to contribute to the systemic inflammation seen in this disorder.[32] The KSHV-associated lymphomas that arise in association with MCD are not nodal equivalents of PEL; rather these plasmablastic lymphomas are uniformly EBV negative and express IgM λ.[16]

Diagnostic and Therapeutic Considerations

The requisite finding in PEL is a lymphomatous effusion, which can be pleural, pericardial, or peritoneal, without associated lymphadenopathy or masses, arising in the setting of immunocompromise. Often, patients with HIV/AIDS will present with PEL in addition to other KSHV-associated diseases, such as Kaposi sarcoma and MCD, so thorough evaluation and staging should be undertaken at diagnosis. On cytologic examination, the PEL tumor cells are large with prominent nucleoli. The effusion cells are clonal B cells with CD45 positivity but typically lack other specific B-cell lineage markers, although CD30 and CD38 positivity can be seen. BCL6 mutations are frequently detected. Tumor cells always harbor KSHV as demonstrated by staining for KSHV-associated latency-associated nuclear antigen-1 (LANA-1). In MCD there is characteristically λ light chain restriction.[33] This does not reflect clonality as assessed by study of Ig DNA rearrangements. Rather it reflects a tendency for the virus to selectively infect cells expressing λ or to selectively drive such cells to proliferate.

Treatment of PEL is most commonly combination chemotherapy. Outcomes remain quite poor. Treatment of MCD with targeted therapies has been more successful, including the use of rituximab and IL-6 inhibition.[34,35] Antivirals such as ganciclovir and valganciclovir have shown clinical activity in MCD, because viral lytic replication is a feature of this disease.[36]

HUMAN T-LYMPHOTROPIC VIRUS-1

Viral Biology

HTLV-1 is a retrovirus with a single-stranded RNA genome.[37,38] Following infection there is reverse transcription and integration of proviral DNA into the host genome. HTLV-1 infects a variety of cell types but persists in $CD4^+$ T lymphocytes. Viral infection within the host is spread from cell to cell through direct cell-to-cell contact. As with EBV, the proliferation of HTLV-1–infected lymphocytes plays a central role in ensuring viral persistence.

The HTLV-1 protein Tax plays a central role in T-lymphocyte immortalization and transformation (Fig. 82-4).[37,39] Tax affects NFκB and the serine/threonine kinase AKT pathways with diverse proliferative and antiapoptotic effects. As with some of the immunodominant EBV antigens expressed in proliferating lymphocytes, Tax expression is targeted by cytotoxic T cells. Another viral protein, Hbz, suppresses Tax expression, allowing transformed T cells to elude immune surveillance.[40] Tax interferes with various DNA repair pathways and induces reactive oxygen species, facilitating the development of aneuploidy.[37,39] Tax leads to functional inactivation of p53 and may interfere with the spindle assembly checkpoint that normally operates in mitosis to preserve euploidy.

Epidemiology of Viral Infection and Adult T-Cell Leukemia/Lymphoma

HTLV-1 is endemic in particular regions of Japan, Africa, South America, and some Caribbean islands.[40,41] As assessed by seroprevalence, rates up to 37% are found on the southwestern Japanese islands of Shikoku, Kyushu, and Okinawa, whereas most other areas of Japan have an intermediate prevalence of 1% to 5%. In the United States

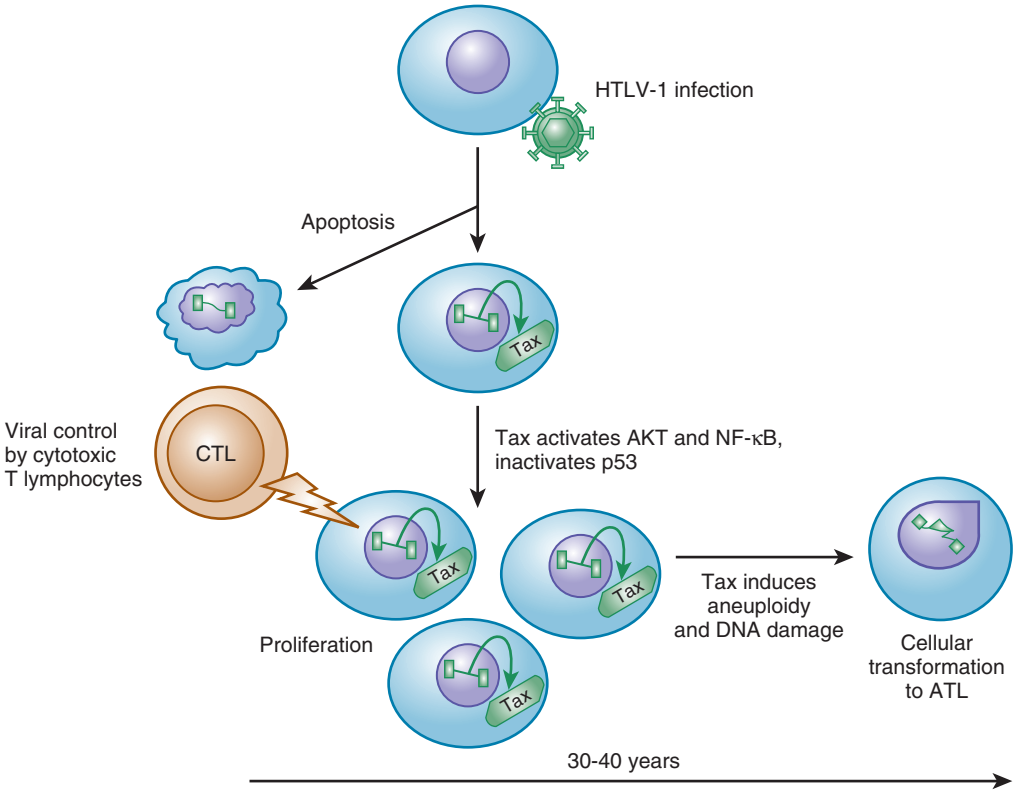

Figure 82-4 HTLV-1 AND THE EVOLUTION OF ADULT T-CELL LEUKEMIA/LYMPHOMA. Following HTLV-1 infection, many cells undergo apoptosis, but some infected $CD4^+$ T cells are driven to proliferate by the effects of Tax on the nuclear factor kappa-B (NFκB) pathway and on the AKT pathway. Tax is also suggested to result in inactivation of p53, aneuploidy, and deoxyribonucleic acid (DNA) damage. Over many decades malignancy evolves. *HTLV-1,* Human T-lymphotropic virus-1.

the incidence in blood donors is 0.025%. It has been estimated that about 20 million individuals are infected worldwide. The major mode of transmission in endemic areas is from mother to child in breast milk, although infection is also transmitted through sexual intercourse, transfusion of cellular blood products, and the sharing of needles and syringes. Evidence has been presented that HTLV-1 infection persists in association with certain human leukocyte antigen (HLA) types and may be more readily transmitted from mother to child when these HLA types are shared.

ATL is more common in men than in women and typically presents in the fourth or fifth decade of life. Perhaps as a function of the long latency period, cases of ATL following blood transfusion or needle sharing are vanishingly rare. The lifetime risk for ATL has been estimated to be in excess of 6% in men who are HTLV-1 carriers in an endemic region of Japan, although in other settings the risk may be much lower.[42] As with EBV, the subset of the infected population that develops lymphoma is quite small.

Adult T-Cell Leukemia/Lymphoma Diagnostic Considerations

There is a spectrum of HTLV-1–associated leukemia/lymphoma.[38] Twenty percent of ATL cases present with a lymphomatous subtype dominated by lymphadenopathy and hepatosplenomegaly. Cutaneous infiltration, lytic bone lesions, malignant effusions, and involvement of the CNS and other extranodal sites are not uncommon.[40] Hypercalcemia is common, particularly in leukemic forms. Presentations reflecting immune dysfunction such as strongyloidiasis with dissemination, *Pneumocystis jiroveci* pneumonia (PJP), mycobacterium, or cryptococcal infection are common. In the leukemic subtype of ATL, the classic findings on peripheral blood smear are lymphocytes with flower-shaped nuclei (Fig. 82-3, *C*).

Histologically ATL shows lymph node effacement by large, atypical T cells usually expressing $CD4^+$, $CD25^+$, and $CD52^+$, with variable CD30 and CD15 expression. Aneuploidy is consistent, although characteristic cytogenetic abnormalities have not been identified. Serologic analysis confirms the presence of HTLV-1 infection.[38]

Therapies Specific to HTLV-1 ATL

ATL is an aggressive lymphoma with poor responses to chemotherapy, high relapse rates, and low overall survival. More indolent chronic and smoldering forms are also recognized. Combination chemotherapy regimens used in the treatment of other lymphomas or leukemias are commonly used, but no standard regimen has emerged.[38,43] Several antivirals used in the treatment of HIV infection have activity against HTLV-1. Among them are zidovudine and lamivudine. The combination of interferon and zidovudine has yielded promising results, particularly in the leukemic subtype.[38] Proteasome and histone deacetylase (HDAC) inhibitors have attracted interest. Given high CD25 and CD52 expression in ATL, the efficacy of monoclonal antibodies aimed against these two receptors has been investigated. Thus far alemtuzumab, an anti-CD52 monoclonal antibody, may have some activity in ATL based on small phase II studies and case reports.[44,45] Arsenic trioxide combined with interferon-α has been shown to induce remissions in relapsed, refractory patients with ATL, although durable responses were limited. In a trial of 20 ATL patients, all-trans retinoic acid was used with 40% achieving remission. Allogeneic hematopoietic transplantation has been increasingly recognized as an effective therapy for ATL.[46,47]

HIV-ASSOCIATED LYMPHOMAS

Viral Biology and Pathogenesis

HIV-1 is a retrovirus that infects $CD4^+$ T cells and monocytes.[48,49] It appears to establish a lifelong reservoir in $CD4^+$ T cells.[50] Viral infection may lead to cell death or establishment of latency in resting cells. HIV infection is spread either through new rounds of virion production with cellular infection or cell-cell fusion. There is no evidence to suggest that infected cells are driven to proliferate. This is in contrast to HTLV-1 and EBV, where proliferation of infected cells appears to play a key role in establishing the long-term viral reservoir and perhaps in mediating lymphomagenesis. The lymphomas that are increased in HIV-infected patients (Table 82-4) are of B-cell lineage, and there is no substantial evidence that HIV infection of B cells is important in the pathogenesis of these lymphomas. Rather it appears that the HIV infection compromises cellular immunity, decreasing immune surveillance of EBV- and KSHV-infected B cells. In addition, HIV infection stimulates proliferation of B lymphocytes and perhaps genetic aberrations in the proliferating cells.[51] Many possible mechanisms have been invoked, including (1) direct stimulation of B cells by HIV antigens or antigens associated with opportunistic infection; (2) stimulation of B cells by cellular proteins (CD40 ligand) incorporated into the HIV virion leading to expression of activation-induced deaminase, an enzyme that mediates double-strand DNA breaks; and (3) dysregulation of B cells as a consequence of T-cell dysfunction.[16,51,52]

There is also some evidence that host biology may contribute to lymphomagenesis. In particular, there are a variety of genetic polymorphisms that influence susceptibility to HIV-1 infection, such as CCR5-Δ32.[53,54] Individuals who are homozygous for this polymorphism are much less likely to be infected by HIV than others. Some evidence has emerged to suggest that in heterozygotes who are infected, HIV progression is slowed and there is less likelihood of lymphomagenesis. Many of these lymphomas are associated with EBV, KSHV, or both (see Table 82-4).

Epidemiology

Lymphoma is increased in all HIV risk groups, in contrast to Kaposi sarcoma, which is rarely seen in injection drug users (or in hemophiliacs in an earlier era).[55] There is a well-established relationship between $CD4^+$ cells per cubic millimeter overall and the risk for lymphoma, but the relationship is complex and differs among lymphomas (see Table 82-4).

The incidence of non-Hodgkin lymphoma (NHL) in the HIV population, particularly PCNSL (Fig. 82-5, *A* to *C*), has decreased with the widespread use of highly active antiretroviral therapy (HAART), although HIV patients on HAART still carry an increased risk for lymphoma compared to the HIV-negative population.[55] In the HAART era, HIV patients on average have higher $CD4^+$ counts (often greater than 100 cells/mm^3) when diagnosed with lymphoma as compared to the pre-HAART era. Among HIV patients with very low $CD4^+$ counts,[56] NHLs are still seen at rates similar to the pre-HAART era. Patients with HIV are now living much longer because of effective antiretroviral regimens and decreased rates of opportunis-

Table 82-4 HIV-Associated Lymphoma

Lymphoma	CD4 Association (cells/mm^3)	EBV Association (%)	Other Cofactors

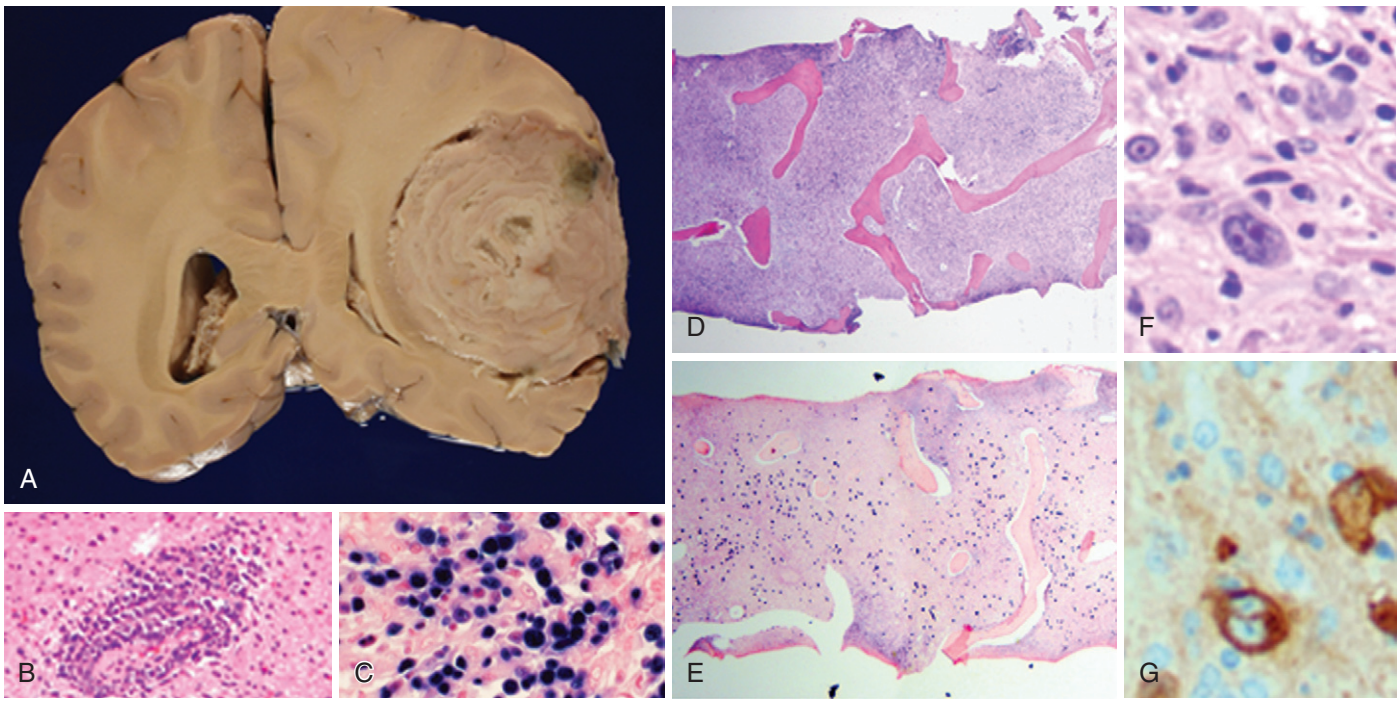

Figure 82-5 EXAMPLES OF HUMAN IMMUNODEFICIENCY VIRUS (HIV)–RELATED LYMPHOMAS. Primary central nervous system (CNS) lymphoma in HIV+ patients (**A** to **C**). Gross appearance (coronal section) of the brain from an autopsy of a 24-year-old HIV+ female patient with temporoparietal mass due to a primary CNS lymphoma (**A**). The patient died from uncal and cingulate herniation. Biopsy section from another patient showing a perivascular infiltrate of large lymphoma cells. This is the typical pattern of involvement by CNS lymphoma (**B**). The cells were shown to be $CD20^+$ B cells and were EBER+ (**C**). A diagnosis can be made without biopsy when magnetic resonance imaging studies show characteristic features and EBV is demonstrated in the cerebrospinal fluid by polymerase chain reaction (see box on AIDS Primary Central Nervous System Lymphoma). Hodgkin lymphoma extensively involving the bone marrow in an HIV+ patient with stage IVB disease (**D** to **G**). The bone marrow biopsy was entirely replaced with Hodgkin lymphoma associated with dense sclerosis (**D**). An EBER study shows scattered positive cells throughout the marrow (**E**), corresponding to the Hodgkin and Reed-Sternberg cells (**F**), which were $CD30^+$ as illustrated (**G**). Hodgkin lymphoma infrequently involves the bone marrow in HIV-negative cases but some HIV+ patients can first present with extensive bone marrow disease (see box on HIV Hodgkin Lymphoma). *(**A** courtesy Dr. Peter Pytel, University of Chicago.)*

HIV Hodgkin Lymphoma

A 42-year-old human immunodeficiency virus (HIV)–positive patient, on highly active antiretroviral therapy (HAART) with a CD4 count of 324 cells/mm^3 and undetectable viral load, presents with fever, weight loss, and a palpable axillary lymph node. Hodgkin lymphoma (HL) is diagnosed on excisional biopsy, and Epstein-Barr virus (EBV) positivity is demonstrated by Epstein-Barr–encoded RNA (EBER) in the Reed-Sternberg tumor cells. Although he lacks additional lymphadenopathy, a bone marrow biopsy is performed, and it shows involvement by HL. He has stage IVB disease. *Pneumocystis jiroveci* pneumonia prophylaxis is started despite adequate CD4 count in anticipation of chemotherapy. His HAART regimen is reviewed for potential antiviral-chemotherapy drug interactions. He receives six cycles of full-dose, first-line chemotherapy and achieves a complete remission.

tic infection. As a result, malignancy has emerged as the major cause of mortality in HIV populations with access to antiretroviral therapy.[57,58]

With the widespread use of HAART, the incidence of HL in HIV-seropositive patients has not declined; patients with $CD4^+$ counts between 150 and 199 cells/mm^3 actually have higher risk for HIV-associated HL than patients with $CD4^+$ counts of less than 50 cells/mm^3.[59]

Diagnostic Considerations Specific to Lymphoma in Patients With HIV

Lymphomas in HIV-infected patients are more likely to present with B symptoms such as fever and night sweats, and advanced stage, including bone marrow, extranodal, and CNS involvement. Thus the approach to diagnosis is somewhat different than the approach in the HIV-negative patient.

Unexplained fever and sweats in an HIV-seropositive patient, even in the absence of lymphadenopathy, are sufficient to warrant consideration of HL. Patterns of disease involvement also differ in HIV-infected patients. Contiguous spread so characteristic of classic HL in other settings is less common in HIV HL. Bone marrow–only presentations of HL are not uncommon (Fig. 82-5, *D* to *G*), and the possibility of HL should be in the differential diagnosis even in the absence of lymphadenopathy.

Patients with HIV-associated NHL have higher rates of extranodal involvement, including bone marrow and CNS disease, as well as higher stage disease and more aggressive tumors on average.[72] Therefore it is recommended that all HIV-seropositive patients with aggressive NHL undergo a diagnostic lumbar puncture. The routine use of CNS intrathecal chemotherapy prophylaxis in all HIV-seropositive NHL patients is controversial but reasonable and typically done in particularly high-risk patients, such as those with BL, marrow or testicular involvement, or extranodal disease.

Imaging is often more difficult to interpret in HIV patients than in other settings. Lymphadenopathy associated with HIV infection or opportunistic infection is common, and the presumption that enlarged lymph nodes reflect the presence of lymphoma in patients with known lymphoma or history of lymphoma is not as safe as in

AIDS Primary Central Nervous System Lymphoma

In acquired immunodeficiency syndrome (AIDS) primary central nervous system lymphoma (PCNSL), Epstein-Barr virus (EBV) polymerase chain reaction of the cerebrospinal fluid is positive approximately 90% of the time and rarely positive in patients with AIDS but without PCNSL. When EBV is detected in the cerebrospinal fluid of an AIDS patient, coupled with characteristic magnetic resonance imaging findings, this is sufficient to diagnose AIDS PCNSL without a confirmatory brain biopsy.

other settings. Positron emission tomography–computerized tomography (PET-CT), although useful, must also be interpreted with caution insofar as HIV infection itself, opportunistic infection, and immune reconstitution following the initiation of antiretroviral therapy are all associated with signal on metabolic imaging with fluorodeoxyglucose.

$CD4^+$ counts can help to guide evaluation insofar as $CD4^+$ counts of greater than 300 cells/mm^3 are typically associated with BL or HL,[60] whereas these diagnoses would be unlikely in patients with very low $CD4^+$ counts of less than 50 cells/mm^3 (see box on AIDS Primary Central Nervous System Lymphoma).[61]

Treatment

Aggressive chemotherapy for HIV-associated lymphoma was initially associated with morbidity and mortality related to immunocompromise. A phase III randomized study identified a reduced-dose regimen as preferable to standard dose.[63] Lower doses were not associated with higher lymphoma cure rates but were associated with less chemotherapy-related morbidity and mortality. However, with the evolution of supportive care, including PJP prophylaxis and neutrophil growth factors, tolerance of chemotherapy improved. With effective antiretroviral therapy, long-term outcomes improved as well.[64,65] And with full-dose therapies, some evidence emerged to suggest that stage-for-stage outcomes might be as good or better in patients with HIV-associated lymphoma compared to those without HIV.[66] At the outset of therapy a series of questions must be addressed.

Regimen

Rituximab, cyclophosphamide, hydroxydaunomycin, vincristine, and prednisone (R-CHOP); and rituximab, infusional etoposide, prednisone, vincristine, cyclophosphamide, and hydroxydaunomycin (R-EPOCH) have emerged as standard regimens.[67,68] As in the treatment of DLBCL in patients without HIV infection, the value of infusional chemotherapy remains controversial. A recent pooled retrospective analysis favored the infusional regimen.[69] However, insofar as the trials were conducted sequentially (R-CHOP between 1998 and 2002, and R-EPOCH between 2002 and 2006), it is difficult to exclude other factors such as the availability of better antiretroviral agents, improvements in supportive care, or changes in the population studied. However, there is general agreement that rituximab improves outcome, at least in patients with $CD4^+$ counts of greater than 50 cells/mm^3.

BL typically requires more intensive treatment regimens than those used for DLBCL.[70] Thus there has been concern about using these regimens in the HIV-seropositive population. A small retrospective study of cyclophosphamide, vincristine (Oncovin), doxorubicin, and methotrexate (CODOX-M)/ifosfamide, etoposide, and cytarabine (IVAC) for BL that included 14 patients with HIV showed HIV-seropositive patients to have similar progression-free survival, overall survival, and complete response rates as compared to the HIV-negative BL patients. In a prospective Spanish study, HIV-seropositive and HIV-seronegative BL patients were treated with six cycles of intensive chemotherapy and rituximab and were found to have comparable outcomes regardless of HIV status.[71] In this study all HIV-seropositive patients were required to be on HAART to enroll, and the majority had $CD4^+$ counts of greater than 200 cells/mm^3. Granulocyte colony-stimulating factor support was used throughout chemotherapy cycles, as well as PJP and other antimicrobial prophylaxis. Differences in induction-related mortality, duration of neutropenia, progression-free survival, or overall survival were not detected, although HIV-seropositive patients did have significantly more severe mucositis and infectious complications.

Dose

Most would agree that dose reduction is appropriate in patients with low $CD4^+$ count (<100 cells/mm^3), history of ongoing opportunistic infection, performance status below 75%, or compromised organ function. Some regimens begin with a 50% dose reduction in cyclophosphamide dose for $CD4^+$ count of less than 100 cells/mm^3 with a built-in dose escalation for the next cycle if well tolerated.[64,68]

Chemotherapy regimens of varying intensity depending on $CD4^+$ count, performance status, and International Prognostic Index score have been studied, including a comparison of low-dose CHOP to standard-dose CHOP, with no differences found in overall survival based on the intensity of the chemotherapy regimen.[66] In patients with very low $CD4^+$ counts, low-dose chemotherapy is a reasonable treatment option, while maintaining the possibility of long-term disease-free survival in some.

Antiretroviral Therapy

A few key special issues in considering concurrent antiretroviral and lymphoma therapy include concerns about shared toxicities, drug-drug interactions, and risk for inability to comply with consistent antiretroviral dosing. Zidovudine is myelosuppressive and can exacerbate pancytopenia associated with lymphoma therapy. If patients are already on a zidovudine-containing regimen, it is generally possible to substitute an alternative regimen before the initiation of lymphoma therapy. Many antiretroviral agents alter the metabolism of drugs used in lymphoma treatment. This has been a particular concern when infusional chemotherapy regimens are used, and some investigators have chosen to stop chemotherapy before initiation of such regimens.[64] However, in trials involving infusional chemotherapy that allowed patients already on a stable antiretroviral regimen to remain on that regimen during lymphoma treatment, major problems were not noted.[68] Nausea and vomiting associated with chemotherapy regimens may interfere with regular antiviral dosing. Intermittent antiretroviral therapy raises concerns about the development of a resistant strain of HIV. Because of the concern that initiation of antiretroviral therapy with cytotoxic chemotherapy might result in such resistance, many recommend delaying initiation of antiretroviral therapy until an appropriate regimen to control nausea and vomiting is established. Stopping antiretroviral therapy also carries with it some risks. When antiretroviral therapy includes drugs with different half-lives, stopping treatment may result in the longest-lived agent being present in the absence of other antiretroviral agents. This is particularly an issue for long-lived nonnucleoside reverse transcriptase inhibitors. Even a single dose of such agents in the absence of other antiretroviral agents may lead to resistance to that class of agents. Thus when an interruption of antiretroviral therapy is planned, specific strategies have been advocated, including a "staggered stop" or a change to a regimen with components that have similar half-lives.[62]

For patients already on antiretroviral treatment at the time of lymphoma diagnosis, the particulars of the regimen should be considered during the pretreatment evaluation. Atazanavir and indinavir are associated with hyperbilirubinemia as a result of UGT1A1 inhibition.[62] This is an unconjugated hyperbilirubinemia similar to that occurring with Gilbert syndrome. Elevated total bilirubin in such patients is not indicative of hepatic involvement or other serious hepatic dysfunction and should not guide decisions about

chemotherapy dose adjustments. Ritonavir inhibits the clearance of midazolam, phenytoin, and voriconazole and other agents metabolized by the cytochrome P-450 CYP3A4 pathway.

Supportive Care

Although PJP prophylaxis is recommended only when the $CD4^+$ count is less than 200 cells/mm^3 for HIV patients not receiving cytotoxic chemotherapy, prophylaxis is universally recommended for HIV patients receiving cytotoxic chemotherapy. The following are also commonly used: fungal prophylaxis with fluconazole; herpes simplex and varicella prophylaxis with acyclovir, valacyclovir, or famciclovir; quinolone prophylaxis when neutrophil counts fall below 1000 cells/mm^3; and granulocyte growth factors.

Bone Marrow Transplantation in HIV Patients

Autologous bone marrow transplant has been successful in HIV-seropositive NHL patients, with these patients having adequate stem cell mobilization, nonrelapse mortality rates comparable to those for HIV-negative patients, count recovery within 2 weeks of stem cell rescue, and maintained control of HIV viral loads and $CD4^+$ counts after high-dose chemotherapy.[73,74] There have also been successful reduced-intensity allogeneic bone marrow transplants in HIV-seropositive patients, making the possibilities for treating HIV patients with NHL even more vast, even in those patients with chemotherapy-resistant disease (see box on Autologous Bone Marrow Transplant in an HIV-Seropositive Hodgkin Lymphoma Patient).[75]

HEPATITIS C VIRUS

Viral Biology and B-Lymphocyte Proliferation

HCV is an enveloped positive-strand RNA virus.[76,77] Infection involves interactions between E2, a viral structural protein with two hypervariable regions, and a cellular protein CD81 present on hepatocytes and B lymphocytes. A polyprotein is translated from viral RNA and is cleaved by cellular and viral proteases, including NS3, to yield proteins required for viral replication. The RNA-dependent RNA polymerase that replicates the viral genome lacks proofreading capacity, thus generating genetic heterogeneity among viral progeny. Viral replication occurs predominantly in the liver, but some evidence suggests that B cells may also be infected.

Chronic infection can be associated with mixed cryoglobulinemia, a systemic vasculitis that results from clonal expansion of B cells producing an IgM autoantibody against IgG, leading to deposition of immune complexes on endothelial surfaces, resulting in inflammation.[78] Several hypotheses have been advanced with regard to how HCV might drive B-cell proliferation. There is controversy as to whether infection of B cells plays any role in this process. A lymphoma cell line that produces infectious HCV has been reported. Even in the absence of infection of B cells, interaction of the HCV E2 protein with CD81 on B cells may drive B-cell proliferation or lower the threshold for other B-cell stimuli to drive proliferation. Ig signaling may be activated by Ig-virus complexes, and Toll-like receptor 7 signaling may be activated by viral RNA. Finally, it is noted that E2 binding triggers expression of activation-induced deaminase, an enzyme that is important in generating somatic hypermutation and that has also been implicated in mediating mutations thought to play a role in DLBCL lymphomagenesis.[77]

Autologous Bone Marrow Transplant in an HIV-Seropositive Hodgkin Lymphoma Patient

A 38-year-old human immunodeficiency virus (HIV)–positive patient with $CD4^+$ count of 485 cells/mm^3 is diagnosed with classic Hodgkin lymphoma (HL) and treated with doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD), achieving a complete remission. Two years later he presents with retroperitoneal lymphadenopathy and is found on biopsy to have relapsed HL. He is treated with salvage chemotherapy with complete response, as well as good performance status and no active infections. His HIV remains well controlled on antiretroviral therapy. He is deemed an excellent candidate for high-dose therapy and undergoes consolidation with autologous bone marrow transplant.

Epidemiology of Viral Infection and Associated Lymphoma

The association between HCV and lymphoma was first recognized in patients with HCV-associated type II mixed cryoglobulinemia, an autoimmune extrahepatic manifestation of HCV infection.[79] There followed demonstration of an increased risk for certain subtypes of B-cell lymphoma (marginal zone lymphoma [MZL], lymphoplasmacytic lymphoma and to a lesser extent DLBCL in HCV-infected patients).[80-83] For example, in Taiwan the rate of chronic HCV infection in patients with NHL was 11%, 10-fold higher than in the general Taiwanese population.[84] Among HCV-infected patients with lymphoma, nodal and splenic MZL, but not mucosa-associated lymphoid tissue (MALT) lymphomas, were increased. The HCV-lymphoma association is more apparent in some countries than others, with the association being established most clearly in Italy and Japan. A multitude of studies in regions or countries where HCV infection is less prevalent have failed to identify any association with lymphoma.[85-87]

Further evidence in support of an etiologic relationship comes from studies in which successful treatment of HCV was followed by lymphoma regression.[88] The most dramatic illustration comes from patients with splenic lymphoma with villous lymphocytes treated with ribavirin and interferon.

Certain HCV genotypes may confer increased risk for NHL, with genotypes 2a/III and 2b/IV seen more frequently in the HCV-seropositive patients that develop NHL.

Diagnostic Considerations

In contrast to EBV-, KSHV-, or HTLV-1–associated tumors, there is no established role for studies demonstrating HCV nucleic acid or protein in tumor cells. Thus serologic study and measurement of HCV copy number are the only tools available for inferring an association. We recommend checking HCV serologic characteristics in all patients with B-cell lymphomas most commonly associated with chronic HCV infection.[89] In addition, screening patients with chronic HCV for a monoclonal gammopathy and cryoglobulinemia may be of benefit to identify patients at highest risk for malignant transformation. Elevated serum γ-globulin levels have been found to be a predictor of NHL among patients with type II mixed cryoglobulinemia.[90] In patients who are HCV seropositive, we evaluate HCV RNA in plasma.

Therapy

In patients with indolent lymphomas and untreated HCV infection, antiviral treatment may obviate the need for cytotoxic chemotherapy and should be considered as an initial therapeutic strategy. The studies showing that antiviral therapy may lead to regression of HCV-associated lymphomas involved treatment with ribavirin and interferon. In the last year new antiviral agents have become available, notably protease inhibitors specific for the HCV protease. Likelihood of response to older therapy is a function of viral genotype, host genetics (IL28R polymorphisms play a critical role in response to

protease inhibitors) and other factors. The field is rapidly evolving, and colleagues with specific expertise in appropriate antiviral approaches should be consulted.[76]

Rituximab has posed an interesting dilemma for the treatment of patients with HCV and lymphoma. It has been reported that HCV plasma RNA increases following rituximab treatment, and there is certainly the possibility that elimination of B cells for 3 to 18 months following treatment may compromise humoral responses to the evolution of HCV quasispecies. However, in studies to date overall survival is not inferior.[91] Similarly, combination chemotherapy is safe in patients with HCV infection.[92] Rituximab is specifically recommended for the treatment of HCV-associated cryoglobulinemia (although as in the treatment of Waldenström macroglobulinemia, it must be appreciated that the initial response to rituximab may be an increase in the IgM paraprotein level, necessitating plasmapheresis).

Aspects of Therapy

With regards to the use of rituximab to treat B-cell lymphomas in patients with HCV, overall survival is not inferior, although there do appear to be increased rates of hepatotoxicity and rises in HCV viral load during therapy. Similarly, combination chemotherapy is safe in patients with HCV infection, although HCV RNA levels can rise during treatment. Interestingly, patients with HCV and splenic MZL have had regression of their tumors with treatment for HCV infection with interferon-α and ribavirin, an effect not seen in HCV-negative patients with splenic MZL treated with the same regimen.

FUTURE DIRECTIONS

In this chapter a variety of virus-associated lymphomas and lymphoproliferative diseases have been reviewed. For most of these lymphomas, standard antiviral drugs do not have a role in treatment. There are, however, several exceptions, and these are worth highlighting. Antiviral therapy for HCV-associated splenic lymphoma with villous lymphocytes is accepted as a standard approach and likely has a role in the treatment of other HCV-associated indolent lymphomas. Similarly, ganciclovir or valganciclovir appears to have a role in the management of MCD associated with KSHV in HIV patients. And of course there is an established role for antiretroviral therapy in the treatment of HIV patients with malignancy. There are virus-targeted therapies that are broadly accepted as standard, including adoptive immunotherapy with EBV-specific T cells for PTLD. The use of targeted T cells also has promise in other settings, including EBV-associated HL. Other virus-targeted therapies are being developed. Some involve vaccination; others involve induction of viral genes in tumor cells, rendering them more susceptible to pharmacologic treatment. Finally, it may ultimately be possible to prevent some kinds of lymphoma by preventing viral infection or altering the host response to viral infection.

CHAPTER 83

MALIGNANT LYMPHOMAS IN CHILDHOOD

Kala Y. Kamdar, John T. Sandlund, Jr., and Catherine M. Bollard

Malignant lymphomas are the third most common malignancy among children and adolescents.[1-3] Among children under 15 years of age, non-Hodgkin lymphoma (NHL) is more frequent; however, in patients up to 18 years of age, Hodgkin disease is predominant. NHLs in children are usually extranodal diffuse high-grade tumors, whereas low- and intermediate-grade nodal lymphomas predominate in adults. These differences are speculated to reflect maturational changes in the function and composition of the immune system.[2] The different histologies explain in part the differing clinical features, disease course, and treatment strategies used in adults and children.

The differences in treatment approach and disease subtypes are less striking in adults and children with Hodgkin disease. However, there are significant challenges in the management of children with Hodgkin disease because of the sequelae of therapy, such as radiation-induced bone growth abnormalities, endocrine dysfunction, and chemotherapy-related sterility. Of greater concern are the radiation- and chemotherapy-related second malignancies and late cardiac deaths. Current trials are examining ways to reduce the toxicity of therapy without compromising the excellent outcome generally achieved.

EPIDEMIOLOGY

The incidence of NHL increases steadily throughout life, in contrast to Hodgkin disease, which has a bimodal age distribution peaking in early and late adulthood.[2] Although NHLs may occur at any age in childhood, they are infrequent among children younger than 3 years of age—the median age at presentation is approximately 10 years. NHL is two to three times more frequent in boys than in girls and is almost twice as common in whites as in African Americans; the reasons for these differences have yet to be determined.[4]

Specific populations at risk for the development of NHL include those with either congenital or acquired immunodeficiency conditions.[5] Inherited immunodeficiency syndromes include Wiskott-Aldrich syndrome, X-linked lymphoproliferative syndrome (XLP), and ataxia-telangiectasia (AT). The recognition of these syndromes in children with newly diagnosed NHL is important for appropriate therapeutic design. For example, involved field irradiation and radiomimetics should be avoided in children with AT. Additionally, children with AT are at increased risk for the development of cyclophosphamide-induced hemorrhagic cystitis; therefore they should receive vigorous hydration and uroprotectants (e.g., MESNA) when receiving any dose of cyclophosphamide. XLP should be considered in any male with a high-grade B-cell lymphoma who either develops a late recurrence (second occurrence) of a high-grade B-cell lymphoma or has a brother with either a high-grade B-cell lymphoma or fatal infectious mononucleosis. Children with acquired immunodeficiency conditions predisposing to the development of NHL include those who have received posttransplant immunosuppressive therapy and those with acquired immunodeficiency syndrome (AIDS).

Differences exist in both the incidence and proportion of histologic subtypes in different parts of the world. For example, the NHLs are very rare in Japan but occur quite frequently in equatorial Africa. Burkitt lymphoma, which accounts for about half of all childhood cancers in equatorial Africa, is the predominant NHL histologic subtype in both equatorial Africa and northeast Brazil.[6] There are also geographic differences in both the clinical and biologic features of certain NHL subtypes.[7,8]

CLASSIFICATION

After Thomas Hodgkin described the disease bearing his name in 1832, various schemes emerged to classify the tumors now collectively referred to as the *NHLs*. Several classification schemes were developed based on histopathologic features and the putative cell of origin. In an attempt to reduce the confusion of multiple classification schemes, the National Cancer Institute (NCI) sponsored a workshop to design a single classification scheme for clinical usage. This scheme, published in 1982 and referred to as the *NCI Working Formulation,* was widely accepted for almost 2 decades. In the Working Formulation, the NHLs of childhood are predominantly diffuse high-grade tumors and can be divided among three major subgroups: lymphoblastic, small noncleaved cell, and large cell lymphomas.

In the past decade, additional classification schemes were designed to improve on the NCI Working Formulation. Because of the problems associated with attempts to classify lymphoid neoplasms into categories based on presumed normal cell counterparts, the International Lymphoma Study Group proposed a classification system for lymphoid neoplasms[9] predicated on a practical approach to categorizing these diseases using available immunologic and molecular genetic techniques in addition to the standard morphologic criteria. This Revised European-American Classification of Lymphoid Neoplasms (REAL Classification) has been endorsed by many of the world's leading lymphoma pathologists, and it has served as the basis for the World Health Organization (WHO) classification of hematopoietic and lymphoid tumors.[10] Both the REAL and WHO classification systems include related lymphoid leukemias and recognize that NHL and acute lymphoblastic leukemia (ALL) represent different stages of evolution within specific morphologically and immunologically defined disease categories—an observation recognized by clinicians caring for children with lymphoid neoplasms and reflected in current clinical practice, which prescribes similar therapies for lymphomas and leukemias of related phenotype.

In the REAL and WHO classification systems, non-Hodgkin lymphomas are classified on the basis of phenotype (B lineage versus T lineage versus NK cell lineage) and differentiation (precursor versus mature). Hence NHLs that occur commonly in children appear in three major categories: lymphoblastic lymphoma (precursor B-cell lymphoma and precursor T-cell lymphoma), mature B-cell NHL (Burkitt and Burkitt-like lymphoma and diffuse large B-cell lymphoma), and anaplastic large cell lymphoma (mature T-cell or null-cell types).

The clinical and biologic characteristics of NHL in children are summarized in Table 83-1 and illustrated in Fig. 83-1, *A-C*.

Lymphoblastic Lymphoma

Lymphoblastic lymphoma (LBL) and acute lymphoblastic leukemia (ALL) are often considered two clinical presentations of the same disease. Patients with a mass and fewer than 25% bone marrow lymphoblasts are designated as having LBL, whereas patients with at least 25% bone marrow involvement have ALL. In contrast to ALL, more than 75% of LBL cases demonstrate a precursor T-cell immunophenotype (T-LBL), with the remainder showing a precursor B-cell immunophenotype (pB-LBL).[11-13]

Epidemiology

LBL constitutes 22% to 28% of childhood NHL. There is a 2 : 1 male predominance for LBL, but the incidence of lymphoblastic lymphoma remains constant across the pediatric age group for both boys and girls.[14]

Table 83-1 Characteristics of Non-Hodgkin Lymphoma in Children

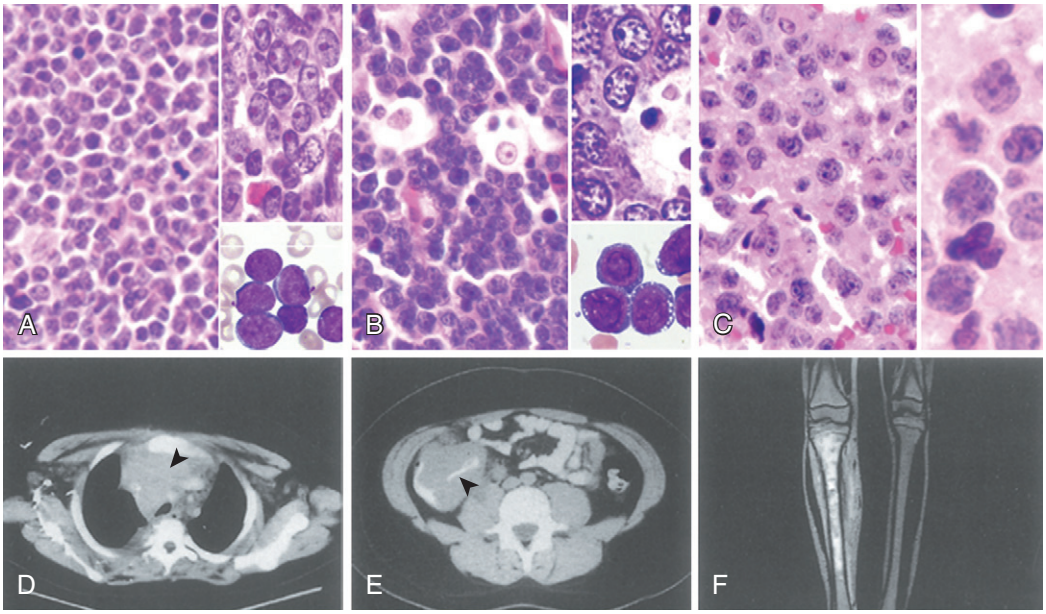

Figure 83-1 HISTOLOGIC AND CLINICAL FEATURES OF THE NON-HODGKIN LYMPHOMAS OF CHILDHOOD. The upper panels (**A** to **C**) demonstrate the appearance in hematoxylin and eosin sections of lymphoblastic lymphoma **(A)**; Burkitt lymphoma/leukemia **(B)**; and large B cell lymphoma, centroblastic with multilobulated nuclei **(C)**. The inserts in **A** and **B** demonstrate the appearance of Wright-stained specimens of the lymphoblasts and the neoplastic cells of Burkitt leukemia/lymphoma, respectively. The lower panels **(D** to **F)** show clinical presentations of the three histologic subtypes of lymphoma: airway compression by lymphoblastic lymphoma of the anterior mediastinum on computed tomography of the chest **(D)**, encasement of the bowel lumen by Burkitt lymphoma on abdominal computed tomography **(E)**, and tibial bone disease in primary lymphoma of the bone **(F)**. *(Reproduced, in part, with permission from Sandlund JT, Downing JR, Crist WM: Non-Hodgkin's lymphoma in childhood,* N Engl J Med *334:1238, 1996.)*

Pathobiology

LBL arises from precursor T or B lymphoblasts at varying stages of differentiation. Morphology is similar to that of ALL, with lymphoblasts of small or medium size and with scant cytoplasm, round or convoluted nuclei, fine chromatin, and indistinct or small nucleoli (see Fig. 83-1, *A*). Stains show positivity for periodic acid-Schiff, variable positivity for Sudan black B and nonspecific esterase, and negativity for myeloperoxidase. Immunophenotyping shows TdT positivity. T-LBL is usually positive for CD7 and surface or cytoplasmic CD3, with variable expression of CD2, CD5, CD1a, CD4, and CD8. CD10 expression is more frequent in T-LBL (40%) than T-ALL (less than 10%), possibly related to maturational stage, with T-ALL more frequently demonstrating an immature phenotype.[13,15,16] B-lineage markers are positive in pB-LBL. Unlike ALL, there are no known cytogenetic prognostic factors for LBL. Recurrent cytogenetic anomalies are seen in about half of childhood T-ALL but have not been well defined in T-LBL. Literature is scarce regarding typical chromosomal aberrations for T-LBL, with most published aberrations reported for T-ALL. The most common chromosomal translocations for both T-LBL and T-ALL involve the T-cell receptor (TCR) gene loci at chromosome 14q11 or 7q34, resulting in the juxtaposition of an oncogenic partner gene with the regulatory region of one of the TCR gene loci and subsequent deregulation of the reciprocal partner gene. Common partner genes seen in T-ALL and T-LBL include *TAL1, MYC, HOXA* gene cluster, and *MYB.* Other chromosomal abnormalities described for T-LBL and T-ALL include *NOTCH1* mutations, alterations of chromosome 9p containing *CDKN2A/CDKN2B* loci, and deletions in chromosome 6p.[17-19]

Table 83-2 Murphy Staging of Non-Hodgkin Lymphoma

STAGE I
Single tumor (extranodal) or involvement of a single anatomic area (nodal), with the exception of the mediastinum and abdomen.
STAGE II
Single tumor (extranodal) with regional node involvement. Two or more nodal areas on the same side of the diaphragm. Two single (extranodal) tumors, with or without regional node involvement, on the same side of the diaphragm. Primary gastrointestinal tract tumor (frequently in the ileocecal area), with or without involvement of associated mesenteric nodes; completely resected.
STAGE III
Two single tumors (extranodal) on opposite sides of the diaphragm. Two or more nodal areas on opposite sides of the diaphragm. Primary intrathoracic tumor (mediastinal, pleural, or thymic). Extensive primary intraabdominal disease. Paraspinal or epidural tumor, regardless of other sites of involvement.
STAGE IV
Any of the above with initial involvement of the central nervous system and/or bone marrow.

Modified from the classification proposed by Murphy (Murphy SB, Fairclough DL, Hutchison RE, et al: Non-Hodgkin's lymphomas of childhood: An analysis of the histology, staging, and response to treatment of 338 cases at a single institution, *J Clin Oncol* 7:186, 1989.)

Clinical Manifestations

The clinical features at presentation vary with primary site and extent of disease spread. Patients with T-LBL frequently present with an anterior mediastinal mass (75%), which may cause respiratory symptoms, airway compromise, dysphagia, or superior vena cava syndrome (see Fig. 83-1, *D*). Pleural effusions are common when a mediastinal mass is present, and lymphadenopathy above the diaphragm is frequent. Bone, skin, bone marrow, central nervous system (CNS), abdominal organs, other lymph nodes, and occasionally testes may also be involved. Children with pB-LBL are less likely to present with a mediastinal mass, but a higher frequency of cutaneous involvement occurs with pB-LBL.[20-23] Bone lesions are also common in pB-LBL.[22,24] CNS involvement at diagnosis is seen in 4% to 5% of patients with LBL.[22,25]

Differential Diagnosis

LBL is distinguished from ALL by having less than 25% bone marrow involvement and from myeloid malignancies being positive for TdT and negative for myeloperoxidase. T-LBL and pB-LBL are differentiated by flow cytometry.

Prognosis (Staging)

After obtaining tissue diagnosis, staging is performed with imaging (computed tomography of neck, chest, abdomen, and pelvis), bilateral bone marrow evaluation, and lumbar puncture. Bone scans are only done if clinically indicated. Childhood NHL, including LBL, is most commonly staged using the Murphy classification (Table 83-2).[26]

With current therapies based on ALL protocols, LBL has a long-term survival greater than 90% in low-stage disease and greater than 80% in advanced-stage disease[27] (Table 83-3). Children with CNS disease have the worst outcome, but CNS disease is less common in T-LBL than in T-ALL. The Children's Oncology Group (COG) demonstrated that minimal disseminated disease at diagnosis has prognostic value, as indicated by flow cytometric evidence of tumor cells in bone marrow. In 99 children with T-LBL treated on the A5971 study, 2-year EFS was 68.1% ± 11.1% for patients with ≥1% T-LL cells in bone marrow by flow cytometry methods, as compared with 90.7% ± 4.4% for patients with lower degree of marrow involvement.[28] Minimal disseminated disease at diagnosis was associated with an increased likelihood of bone marrow or distant recurrence but not local recurrence. On NHL-BFM trials, adolescent females with T-LBL had poorer outcomes than adolescent males despite similar presenting characteristics. In 45 adolescents with T-LBL, the 5-year EFS was 57% for females and 92% for males ($p = 0.004$). This gender difference was not observed in children younger than 15 years old on NHL-BFM trials.[29] One adult study for T-cell ALL has demonstrated poorer outcomes in females than in males,[30] but a prognostic impact of gender has not been found in other pediatric or adult studies for LBL. Although adolescent age itself has not been established as a poor prognostic factor as it has for ALL, adult outcomes for LBL are inferior to pediatric outcomes.[31]

Therapy

Two potentially life-threatening situations requiring urgent intervention must be considered in children with LBL: (1) mediastinal tumor with airway obstruction or superior vena cava syndrome and (2) tumor lysis syndrome. Because of the cardiac and respiratory risks associated with anesthesia or sedation in children with a large mediastinal mass, the least-invasive procedure for obtaining a tissue sample should be chosen. In children with peripheral lymphadenopathy, lymph node biopsy under local anesthesia may be possible. In children who cannot tolerate a procedure, pretreatment with steroids or radiation may be necessary to stabilize the patient. Since pretreatment may diminish the ability to accurately diagnose a patient, a tissue biopsy should be obtained as soon as it is possible to do so safely. Tumor lysis syndrome is characterized by metabolic consequences of the breakdown of lymphoma cells causing renal failure if severe. Hyperuricemia, hyperkalemia, and hyperphosphatemia must be

Table 83-3 Outcomes for Lymphoblastic Lymphoma

Protocol	*n* =	Stage	Regimen	EFS
CCG 551[33]	164	I-IV	LSA_2L_2 (multidrug, cyclic chemotherapy, ± XRT)	64% (5-year)

aggressively managed by hyperhydration, rasburicase and/or allopurinol, and close monitoring. Children with NHL can also present with epidural masses and associated neurologic deficits caused by spinal cord compression. If the diagnosis is known, chemotherapy should be started as soon as possible. If the diagnosis is not known, or if there is a sluggish response to chemotherapy, emergent steroids or low-dose radiation therapy may be considered in consultation with a radiation oncologist.

For stage I and II disease, cooperative group studies have shown that short, pulsed chemotherapy regimens are effective for some pediatric NHL such as Burkitt lymphoma (90% OS) but are inferior for treatment of LBL (60% OS).[32,33] However, the Berlin-Frankfurt-Münster (BFM) group showed excellent outcomes for LBL with extended combination chemotherapy based on ALL treatment with induction, consolidation, and maintenance phases lasting a total of 24 months (90% 5-year EFS).[27] Even patients with stage III and IV LBL had good outcomes on ALL-type therapy.[34,35] This ALL-like therapy has now become standard for LBL (see Table 83-3). The Children's Oncology Group is currently risk-stratifying patients with T-LBL based on the presence of minimal disease in the bone marrow at presentation and on radiologic response to induction therapy, with high-risk patients eligible for randomization to additional therapy. CNS prophylaxis is needed for LBL, but chemotherapy prophylaxis has not proven inferior to prophylactic cranial irradiation in CNS-negative patients, even with advanced-stage disease.[22,36,37] Additionally, the Pediatric Oncology Group did not demonstrate a survival advantage of high-dose methotrexate for T-LBL, although its utility in T-ALL is still being evaluated.[35]

Burkitt Lymphoma

Burkitt lymphoma (BL) was first described by Dennis Burkitt in the 1950s in Uganda.[38] First thought to be endemic to equatorial Africa, it was subsequently observed in Europe and North America. The WHO classification recognizes three variants: (1) sporadic BL, occurring throughout the world and more common in children, adolescents, and young adults; (2) endemic BL, occurring primarily in sub-Saharan Africa and New Guinea, with some unique clinical features but morphologically identical to sporadic BL; and (3) immunodeficiency-associated BL, observed primarily in patients with HIV and less commonly in the setting of other immunodeficiencies. The WHO and REAL classifications also recognize the controversial entity of Burkitt-like lymphoma, with features intermediate between BL and diffuse large B-cell lymphoma (DLBCL). Burkitt-like lymphoma is rare in children, and the clinical value of this classification is unclear. When there is greater than 25% bone marrow involvement, it is designated Burkitt leukemia (FAB L3 subtype of ALL) but is treated similarly to Burkitt lymphoma.[10,39]

Epidemiology

Sporadic BL constitutes approximately 35% to 50% of childhood NHL and is much more common in boys than in girls (4:1 ratio), with a peak incidence between 5 and 14 years of age.[11,14] Endemic BL associated with Epstein-Barr virus (EBV) in more than 85% of cases accounts for approximately half of all childhood cancers in equatorial Africa. In contrast, sporadic BL is most common in the United States and Europe and is associated with EBV in only 15% of cases.[40]

Pathobiology

BL is composed of monomorphic, small, noncleaved cells with round nuclei, clumped chromatin, and basophilic cytoplasm (see Fig. 83-1, *B*). A high uniform proliferation index is seen, with the Ki-67 positivity approaching 100%. The classic "starry sky" appearance of BL seen under low-power microscopy is caused by tingible body macrophages scattered among malignant cells. Burkitt-like lymphoma has a gene expression signature that is similar to Burkitt lymphoma but has more variation in nuclear size and shape, with larger cells and larger nucleoli similar to DLBCL.[41-43] BL cells show mature B-cell features and usually express surface immunoglobulins. B-cell markers such as CD19, CD20, and CD22 are usually present, and the majority express CD10 (CALLA). BL is negative for TdT and BCL-2. CD21, the EBV receptor, is more commonly seen in endemic BL than in sporadic BL.

Characteristic chromosomal translocations suggest that BL develops from genetic aberrations during immunoglobulin gene rearrangement or attempted immunoglobulin class switching in a B-cell precursor. These translocations, usually t(8;14) or infrequently t(8;22) or t(2;8), juxtapose the *c-Myc* gene (involved in cellular proliferation) with immunoglobulin locus regulatory elements, resulting in c-Myc overexpression. In sporadic cases, the predominant chromosome 8 breakpoints usually occur within the *c-Myc* gene, whereas they are upstream of the gene in endemic cases. Other cytogenetic abnormalities, such as gain of 7q and deletion of 13q, are uncommon.[44,45]

Clinical Manifestations

BL is an extremely fast-growing malignancy. The most common primary sites of sporadic BL are the abdomen and the lymph nodes of the head and neck.[46,47] Abdominal disease presentation, which is often associated with nausea, vomiting, and abdominal pain, carries a risk for intestinal perforation, obstruction, and gastrointestinal bleeding. Abdominal lymphoma often arises from the distal ileum

causing intestinal obstruction secondary to intussusception or compression by an expanding mass encasing the bowel (see Fig. 83-1, *E*). BL can involve testes, bone, skin, bone marrow, and CNS. CNS involvement at diagnosis, occurring in about 9% of patients, is associated with a worse outcome.[25] Endemic BL frequently involves the abdomen, jaw, paraspinal region, orbit, and CNS.

Differential Diagnosis

In DLBCL, another mature B-cell lymphoma, the cells are usually larger and additional cytogenetic abnormalities, such as BCL-6 gene rearrangements or t(14;18), may be seen, although these abnormalities are more common in adult DLBCL. Ki-67 staining in less than 95% of the cells or positivity for BCL-2 is helpful in excluding a diagnosis of BL. Burkitt-like lymphoma is a controversial diagnosis with some morphologic features more similar to DLBCL, including larger cells, but commonly with *c-Myc* translocations and a clinical behavior similar to classic BL.[41,48] TdT negativity is helpful in distinguishing BL from pB-LBL.

Prognosis (Staging)

The risk group classification developed by the French Society of Pediatric Oncology (SFOP) is widely used on current protocols incorporating risk-adapted therapy (Table 83-4). This system takes into account whether localized disease has been resected and the adverse prognosis associated with CNS or bone marrow involvement. Localized or CNS-negative advanced-stage cases of BL have greater than 90% long-term survival with current therapies, with approximately 79% event-free survival (EFS) for CNS-positive BL.[49] Cytogenetic abnormalities such as gain of 7q, deletion of 13q, and partial duplication of 1q carry a poor prognosis. Suboptimal response to initial cytoreduction is also associated with worse prognosis, and poor responders are often stratified to more intensive chemotherapy on current regimens. High levels of lactate dehydrogenase (LDH) at diagnosis also carries a worse prognosis and is frequently incorporated in risk-classification schemes. Age greater than 15 years has a worse outcome for mature B-cell malignancies, but this may be primarily due to DLBCL rather than BL.

Therapy

Tumor lysis syndrome must be anticipated as a major risk in newly diagnosed Burkitt lymphoma. To help prevent this complication, children at risk should be vigorously hydrated (3 to 4 L/m^2/day with D_5 ¼ NaCl and 40 mEq/L $NaHCO_3$; there should be no added potassium) and started on allopurinol, a xanthine oxidase inhibitor. The urine pH should be maintained at about 7.0; at a more alkaline pH, phosphorus is less soluble, and at a more acidic pH, uric acid is less soluble. In some cases, mannitol followed by furosemide is required to maintain urine output. Uricolytic agents, which have been used for many years in Europe, directly cleave the uric acid molecule and result in a precipitous drop in serum uric acid levels within a few hours. The use of uricolytic agents (e.g., urate oxidase, uricase, rasburicase) has proven to be superior to allopurinol to reduce rapidly the level of serum uric acid and improve renal function. Rasburicase has significantly reduced the need for hemodialysis consequent to tumor lysis syndrome. Recent protocols incorporate a prophase of reduced intensity to decrease the risk for severe tumor lysis syndrome.[50] In the setting of abdominal BL, intestinal perforation, obstruction, or gastrointestinal bleeding may not occur until after the initiation of chemotherapy as the lymphoma begins to regress.

A multinational cooperative study demonstrated that localized resected mature B-cell NHL (including both BL and DLBCL) could be cured without significant toxicity by two courses of COPAD (cyclophosphamide, vincristine, prednisolone, and doxorubicin) without intrathecal chemotherapy. Four-year OS was 99.2%.[51] Advanced-stage BL requires aggressive combination chemotherapy with CNS prophylaxis (Table 83-5). Cyclophosphamide, methotrexate, and cytarabine at high doses have been used most recently, with or without anthracyclines and epipodophyllotoxins. Therapy should be started as quickly as possible upon presentation, because this tumor grows very rapidly, and subsequent cycles should be administered in an intensive fashion as soon as recovery occurs from the last cycle. CNS prophylaxis is needed—without it, approximately 30% to 50% of patients will relapse in the CNS,[52] whereas only 6% to 11% develop CNS relapse if adequate prophylaxis is given.[25] CNS prophylaxis includes high-dose methotrexate (and cytarabine in high-risk patients) to penetrate the CNS, together with intensive intrathecal chemotherapy. Risk-adapted therapy used in the SFOP LMB-89 study conferred an excellent 5-year EFS of 91% in advanced-stage patients without bone marrow or CNS involvement and approximately 79% to 84% with bone marrow or CNS disease. Treatment intensity was escalated based on tumor burden and response to therapy. These are the best published outcomes to date, but these regimens have significant hematologic toxicity; thus growth factor and blood product support is needed.[49] The French-American-British

(FAB)/LMB-96 study successfully reduced therapy for intermediate-risk (Group B) patients without a compromise in survival. In this study, a reduction in the cumulative dose of cyclophosphamide and omission of a multi-agent maintenance cycle for Group B patients resulted in a reduction in toxicity while maintaining the effectiveness seen on LMB-89.[50] However, intensity of therapy could not be safely reduced for Group C patients.

Rituximab is a mouse/human chimeric monoclonal antibody against CD20, highly expressed in BL and DLBCL. In adults, the addition of rituximab to CHOP chemotherapy is beneficial for DLBCL[53,54] and has been given safely in combination with intensive BL therapy.[55] In children, single-agent rituximab showed activity for BL in a phase II window study for newly diagnosed patients.[56] The Children's Oncology Group is evaluating the safety and efficacy of adding rituximab to the LMB backbone for the treatment of BL.

Local radiation therapy has no role in BL because it is chemosensitive and often diffuse. CNS radiation has been used in the past for CNS involvement at diagnosis but did not show an impact on outcome in this group. Surgery is no longer routinely used for Burkitt lymphoma. However, patients with localized disease resected at diagnosis are eligible for reduced chemotherapy, as noted earlier.

Diffuse Large B-Cell Lymphoma

DLBCL includes a heterogeneous group of neoplasms of transformed B cells, accounting for 10% to 13% of pediatric NHL.[11] Primary mediastinal disease, termed *primary mediastinal B-cell lymphoma (PMBCL),* occurs in 20% of childhood DLBCL cases. DLBCL has some distinctive biologic and clinical features, described in more detail in the following sections.[57]

Epidemiology

The incidence of DLBCL increases with age, being more common in the second decade of life.[14,58] It is rare in children younger than 4 years of age. Although DLBCL is more common in boys than girls (in a 2.1 : 1 ratio), the gender difference is less notable than in BL. PMBCL occurs more frequently in adolescents, with no gender difference.[57]

Pathobiology

Most pediatric DLBCL cases have a germinal-center or postgerminal-center mature B-cell phenotype.[58] Nuclei are usually more than twice the size of normal lymphocytes (see Fig. 83-1, *C*). They express pan-B cell antigens, including CD19, CD20, CD22, and CD79a, with or without surface immunoglobulin. Most express CD10 and BCL6, and approximately 40% express BCL2. However, breaks or translocations in *BCL2* and *BCL6* are rare in pediatric DLBCL. Unlike adult DLBCL, pediatric cases rarely demonstrate the t(14;18) translocation.[57,58] Gene profiling has led to subclassification of adult cases into germinal center B cell–like, activated B cell–like, and type 3 (those not belonging to the first two groups) phenotypes. The great majority of children have the germinal center B cell–like phenotype.[51,58] Of note, this phenotype has a better prognosis in adults, and childhood DLBCL outcomes are better than adult outcomes. Morphologic variants of DLBCL include centroblastic, immunoblastic, anaplastic, and T cell/histiocyte—rich variants.[59] Although DLBCL is clearly heterogeneous, the clinical value of these distinctions is unclear in children.

PMBCL is thought to originate from medullary thymic B cells. B-lineage antigens and CD30 are often positive, but surface immunoglobulin and HLA class I and II molecules are absent or incompletely expressed.[57] *MYC, BCL2,* and *BCL6* genes are not rearranged. PMBCL is associated with gains in chromosome 9p (involving JAK2) and 2p (involving c-rel). They commonly demonstrate inactivation of SOCS1.[60,61] Variable degrees of sclerosis occur in PMBCL,[62] as well as occasional lymphocytes, eosinophils, and Reed-Sternberg–like cells, sometimes leading to confusion with Hodgkin lymphoma.

Clinical Manifestations

DLBCL is often more localized than BL and is less likely to involve the bone marrow or CNS.[25] Nodal disease is more commonly seen in DLBCL than in BL, but extranodal disease is frequent. Common sites of involvement include the abdomen, mediastinum, bone (see Fig. 83-1, *F*), and head and neck, particularly Waldeyer ring. PMBCL is locally invasive and frequently associated with SVC syndrome or airway compression. Pleural or pericardial effusions are present in approximately 40% of PMBCL cases,[62] and kidney metastases are frequent.[57]

Differential Diagnosis

The differential diagnosis of DLBCL encompasses BL, pB-LBL, and nodular lymphocyte predominant Hodgkin lymphoma. BL is distinguished from DLBCL by morphology, although atypical BL shows more pleomorphism than typical BL. BCL2 negativity, high cell proliferation, and translocations involving *c-Myc* may suggest BL but are not definitive. DLBCL, with its mature phenotype, differs from pB-LBL by a lack of TdT expression. DLBCL and nodular lymphocyte predominant Hodgkin lymphoma share some similar features and derive from a common B-cell clone. DLBCL may represent the clonal progression of nodular lymphocyte predominant Hodgkin lymphoma. PMBCL can also be confused with Hodgkin lymphoma and an adequate biopsy is essential for diagnosis. PMBCL and other DLBCL are distinguished clinically—PBMCLs typically reside within the thymic area, whereas mediastinal DLBCLs usually involve mediastinal lymph nodes.

Prognosis (Staging)

Murphy classification is used to stage DLBCL.[63] No difference in outcomes exists between Burkitt lymphoma and DLBCL based on histology, and the treatment is identical in children.[57] The outcome for DLBCL is better for children than adults, with 5-year OS of 90% for children using current therapies. Prognosis is poorer for children who have DLBCL with *c-Myc* rearrangements and for those with PMBCL (5-year EFS of 65% to 70%).[44,62] Adolescent females fared worse than adolescent males with DLBCL on NHL-BFM protocols.[29] In the setting of PMBCL, an LDH level of 500 units/L or more carries a worse prognosis.[62] BCL2 expression is not an unfavorable prognostic factor in children with DLBCL, in contrast to adults with DLBCL.[58]

Therapy

In children, all mature B-cell lymphomas are usually treated similarly with good results. Despite biologic and clinical differences, BL therapy is effective in DLBCL (Table 83-6).[57] Risk-adapted therapy with LMB (SFOP study) or B-NHL (BFM study) backbones consists of short, dose-intense courses of chemotherapy, including steroids, vincristine, high-dose methotrexate, cyclophosphamide, doxorubicin, cytarabine, etoposide, and intrathecal chemotherapy.[34,49,50,64] As described for BL, risk-adapted therapy based on LMB-89 and LMB-96 are also the current standard of care for childhood DLBCL.[49,50] Rituximab can improve adult outcomes for DLBCL when added to CHOP or CHOP-like therapy, but the benefit has not been proven in children.[53,54,65] Adult data suggest that rituximab may allow diminished use of agents with serious acute or late toxicities, warranting further study.[54] Children with localized primary DLBCL of the bone have excellent outcomes in Pediatric Oncology Group studies using

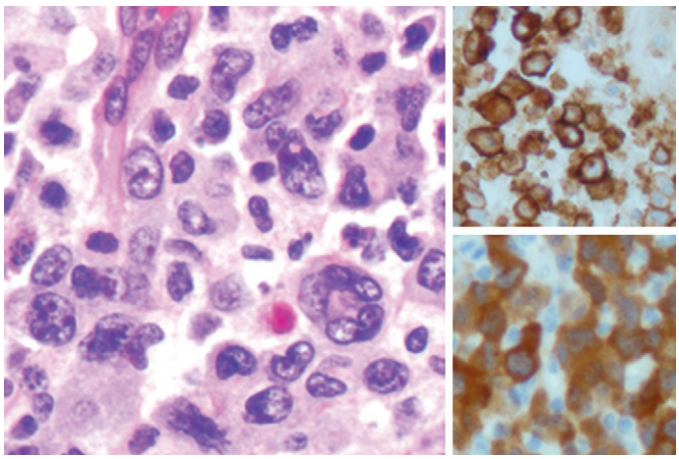

Figure 83-2 HISTOLOGIC AND IMMUNOPHENOTYPIC FEATURES OF ANAPLASTIC LARGE CELL LYMPHOMA. The section shows anaplastic cells including a "wreath cell" and a staining pattern with bright CD30 (Ki-1)-positivity *(top right)* and ALK-positivity *(bottom right)*. The nuclear and cytoplasmic staining by ALK would predict that the case has the t(2;5).

modified CHOP therapy without radiation for a total duration of 9 weeks.[66] Having evolved from BL regimens, DLBCL treatment has traditionally included intrathecal chemotherapy for CNS prophylaxis. Since the risk for CNS involvement is lower for DLBCL than for BL, it is unclear if CNS-directed therapy should be as intensive.[25,57] Local radiation has no role in frontline DLBCL therapy.[57]

Anaplastic Large Cell Lymphoma

Most childhood NHLs previously classified as large cell lymphomas fall into the category of anaplastic large cell lymphomas (ALCLs) in the REAL and WHO classification. This entity was first described in 1985 as a clinicopathologic variant of large cell lymphoma with a predilection for young patients.[67]

Pathobiology

ALCLs are characterized by the proliferation of large, pleomorphic cells with one or more prominent nucleoli (Fig. 83-2). The cells preferentially involve lymph node sinuses and extranodal sites (notably skin, bone, and soft tissue), where they grow in a cohesive pattern. The cells express epithelial membrane antigen (EMA) and CD30 (Ki-1) antigen—a 120-kd membrane-bound molecule and a member of the tumor necrosis factor (TNF) receptor superfamily—previously found in association with Hodgkin disease. A soluble (88-kd) form of the CD30 molecule is found in high levels in the serum of nearly all patients with ALCL.[68] Marked elevation of soluble CD30 levels in patients with ALCL correlates with higher risk for relapse, and soluble CD30 levels correlate with clinical disease status, returning to normal with attainment of complete remission and increasing with disease recurrence.

The anaplastic large cell lymphomas are associated with chromosomal rearrangements involving the long arm of chromosome 5 at position q35.[69] In most cases, this translocation includes material from chromosome 2p23 [t(2;5)(p23;q35)], resulting in the fusion of the NPM nucleolar phosphoprotein gene on chromosome 5q35 to anaplastic lymphoma kinase (ALK), a tyrosine kinase gene on chromosome 2p23. The hybrid protein produced from the translocation links the amino terminus of nucleophosmin (NPM) with the catalytic domain of ALK.[70] Deregulated expression of the truncated ALK may contribute to malignant transformation. The chimeric NPM-ALK protein is clearly oncogenic, perhaps through triggering of antiapoptotic signals via phosphatidylinositol 3-kinase/AKT, although secondary molecular events may be required for lymphomagenesis.

Immunologic and molecular biologic studies reveal that most cases of Ki-1$^+$ anaplastic large cell lymphomas are derived from activated T cells, although cases of non-T cell, non-B cell (null cell), and more rarely, B cell occur.[71] Based on extended testing for T-cell antigens and examination of the configuration of T-cell receptor genes, many null cell cases are, in fact, T-lineage neoplasms, although a minority may be derived from natural killer (NK) cells.[72] The diagnosis of ALCL can be difficult, and many cases are initially misdiagnosed as Hodgkin disease. In many cases, the diagnosis of ALCL can be confirmed by molecular techniques (RT-PCR) to detect the fusion gene resulting from t(2;5). Variant translocations in which ALK is involved with other partner genes on other chromosomes limit the application of RT-PCR for diagnosis. However, the t(2;5) results in the expression of the NPM-ALK fusion protein, whereas the variant translocations result in upregulation of ALK. The ALK1 monoclonal antibody recognizing the formalin-resistant epitope of both the NPM-ALK chimeric protein and normal ALK thus serves as a useful diagnostic reagent for identifying cases of ALCL. It should be noted that the distribution of ALK staining varies depending on the translocation. Further, ALK expression is a feature of inflammatory myofibroblastic tumors (IMT); however, confusion with ALCL can be minimized by testing for other hematopoietic markers, and the distinction is not usually difficult for experienced pathologists.

Clinical Manifestations

ALCL is rare, accounting for approximately 8% to 13% of childhood NHLs and roughly 30% to 40% of the pediatric large cell lymphomas. Approximately one-third of the cases present with localized disease, whereas the majority have advanced disease at presentation, although bone marrow and central nervous system involvement is uncommon.[73] A rare leukemic presentation of ALCL possibly associated with the small cell variant of ALCL has been described. Systemic symptoms (fevers, weight loss) are frequently present in advanced-stage disease. Cutaneous (spontaneously regressing) lesions sometimes accompany disease at other sites, but skin involvement is not universal.[67] A variety of presenting sites—both nodal and extranodal—can occur, including the mediastinum, gastrointestinal tract, and bone. Further, tumors may invade adjacent structures and be associated with ascites and other intraabdominal sites of disease, including kidney, liver, and lymph nodes. The outcome of children with ALCL in most series has been good (with survival rates ranging from 70% to 85%), albeit inferior to that of children with Burkitt and diffuse large B cell lymphomas (Table 83-7).

Diagnosis and Differential Diagnosis

Immunophenotyping and immunohistochemistry is critical for the definitive diagnosis of ALCL. The typical ALCL immunophenotype

Table 83-7 Outcomes for Anaplastic Large Cell Lymphoma

Protocol	*n* =	Stage	Regimen	EFS
POG 8314 and 8719[79]	72	I-II (resected)	CHOP ± maintenance	88% (5-year)*
CCG 5941[76]	86	Nonlocalized	Multiagent, + maintenance	68% (5-year)
NHL-BFM 90[80]	9	I-II (resected)	Multiagent, risk-adapted (short-pulse B-NHL–type therapy)	100% (5-year)
	65	II (nonresected)-III		73% (5-year)
	14	IV and multifocal bone involvement		79% (5-year)
ALCL-99[75]	225	I-IV	Multiagent, risk-adapted, 3-6 cycles chemotherapy	81% (5-year)

is $CD30^+$, $CD15^-$, $CD45^+$, in contrast to Hodgkin lymphoma, which is typically $CD30^+$ and $CD15^+$. More than 60% of cases of ALCL express one or more T-cell antigens ($CD3^+$, CD43, or CD45RO) and ALK protein is detected in most cases (over 60%).

Prognosis (Staging)

The disease stage of ALCL is determined according to the staging system described by Murphy (see Table 83-2).[26] As for other types of childhood NHL, stages I and II are considered limited-stage disease, whereas stage III represents advanced-stage disease. Stage IV is reserved for children with bone marrow or central nervous system involvement. For older adult patients with cutaneous $CD30^+$ ALCL, the 5-year disease-free survival appears to be determined by the extent of limb involvement; however, this has not been shown in children, possibly because primary cutaneous ALCL is rare in the pediatric population.[74]

For systemic ALCL, studies have suggested that the stage of disease may be more important than the expression of the ALK protein. The European Intergroup for Childhood Non-Hodgkin Lymphoma (EICNHL) defined three factors (mediastinal involvement, visceral involvement, and skin lesions) associated with poorer prognosis in childhood ALCL.[75] This group conducted a multivariate analysis (merging preexisting databases from BFM, SFOP, and the United Kingdom Children's Cancer Study Group [UKCCSG] studies) and identified poor prognosis (one or more risk factors) and standard risk groups with 5-year PFS of 61% and 89% respectively. However, it is important to note that this study was not done as a prospective collaborative study. In contrast, the Children's Cancer Group (CCG) Study 5941 (CCG-5941) reported that only bone marrow involvement significantly changed the 5-year survival rate.[76]

The presence of ALK autoantibodies appears to be associated with decreased clinical risk factors and lower clinical stage, resulting in a lower cumulative incidence of relapses.[77] No correlation exists between outcome and the ALK translocation type. However, recently, the SFOP group have shown that for patients with ALK-positive ALCL, the presence of a small cell or lymphohistiocytic component is associated with a worse prognosis.[78]

Therapy

The optimal treatment approach for patients with ALCL has yet to be determined, as evidenced by a wide range of successful treatment strategies. In the United States, children with advanced stage $CD30^+$ ALCL are generally treated with non-ALCL large cell lymphoma regimens, with long-term event-free survival rates ranging from 60% to 75%[75,76,79,80] (see Table 83-7). In a randomized trial performed by the POG, addition of intermediate-dose methotrexate and high-dose cytarabine did not improve on the 70% 4-year event-free survival achieved with APO alone.[81] The BFM reported 3-year EFS of approximately 80% using a Burkitt lymphoma–based strategy.[80] Regimens designed specifically for children with $CD30^+$ ALCL have been developed by the French (SFOP) and German groups.[82] The SFOP also reported the successful salvage of ALCL patients with the weekly administration of single-agent vinblastine.[83] The impact of incorporating vinblastine into two different frontline treatments for ALCL (the BFM B-cell approach [multinational European trial] and APO [COG trial in the United States]) was then studied in randomized fashion. Patients receiving the vinblastine plus chemotherapy regimen had a better EFS in the first year after therapy (91%) than those not receiving vinblastine (74%); however, at the 2-year follow-up, EFS was 73% for both groups.[84] This study also showed that infusing methotrexate 1 g/m^2 over 24 hours was comparable to 3 g/m^2 over 3-hour infusions without intrathecal methotrexate.[85] However, 3 g/m^2 of methotrexate had less toxicity.

Other studies have come to no firm conclusions. For example, (1) the POG-9317 trial demonstrated no benefit of adding methotrexate and high-dose cytarabine to 52 weeks of doxorubicin (Adriamycin), prednisone, and vincristine (Oncovin), or APO, regimen[81] and (2) the CCG-5941 study, which evaluated a more intensive induction and consolidation with maintenance for 1 year total duration of therapy, had similar outcomes but with significant hematologic toxicity.[76]

Relapsed Non-Hodgkin Lymphoma Management

There is no standard treatment for relapsed NHL. Treatment usually consists of intensive chemotherapy to induce a complete or partial response, followed by autologous or allogeneic stem cell transplant. Recent studies suggest that allogeneic transplant may be more effective than autologous transplant for relapsed NHL, particularly for lymphoblastic lymphoma.[86] Outcomes are significantly better for patients with a complete remission before transplant. Radiation may be useful before transplant in selected patients with an incomplete response to chemotherapy.

Outcomes vary by histologic subtype. Relapsed BL and DLBCL is often chemoresistant, and survival is only 10% to 20%. The Children's Oncology Group used rituximab, ifosfamide, carboplatin, and etoposide (R-ICE) for salvage therapy in this population, achieving a 60% response rate (complete and partial).[87] Patients who achieve a complete remission should proceed to stem cell transplant. Relapsed LBL is also frequently chemoresistant, and reported survival is 10% to 40%.[88-90] Salvage regimens used for ALL may be employed for LBL, and nelarabine has demonstrated a 40% response rate in this setting for T-ALL and T-LBL in a phase II COG study.[91] Survival for relapsed ALCL is better than for other non-Hodgkin lymphomas, reaching 40% to 60%.[29,88,92] Vinblastine monotherapy as salvage therapy resulted in a complete remission rate of 83% in one study.[93] Brentuximab vedotin, an antibody against CD30, has been used successfully in adults with relapsed ALCL but has not been well studied in children yet.[94] Crizotinib, an ALK inhibitor, has also shown promise in adults in early clinical trials for relapsed ALCL patients and is undergoing phase I evaluation in children.[95] Autologous transplant has been

used successfully for some patients, but allogeneic transplant may have better outcomes and is preferred for patients with bone marrow or CNS involvement, early relapse, and CD3-positive ALCL.[29,86,96]

Posttransplant Lymphoproliferative Disorder

The biology of posttransplant lymphoproliferative disorder (PTLD) is discussed in Chapter 52. Therefore this section merely serves to summarize the issues specific for pediatric patients with this diagnosis. The pediatric populations where PTLD is most frequently seen include patients with congenital immune deficiencies and patients after bone marrow or solid organ transplant. A particularly high risk is seen in stem cell transplant recipients with underlying immunodeficiencies such as Wiskott-Aldrich syndrome.[97] Patients with primary, congenital immunodeficiencies such as X-linked agammaglobulinemia and ataxia telangiectasia have an incidence of EBV-associated lymphoproliferative disease (LPD) ranging from 0.7% to 15%.[98] The incidence of PTLD after solid organ transplant is higher in children than in the adult population. The disease is heterogeneous but in children it is most frequently of B-cell origin and associated with EBV. In the United States, approximately 150 new cases are diagnosed in children each year.

Numerous therapeutic approaches to PTLD have been explored in children but generally there has been a paucity of multicenter collaborative studies for this disease. Withdrawal or reduction of immunosuppression is often considered as firstline therapy for PTLD, but the success of this maneuver depends on whether the patient can recover sufficient immune system function to eradicate EBV-infected B cells. For the pediatric HSCT patient, strategies have included reduction in immune suppression, rituximab,[99] donor lymphocyte infusions,[100] and EBV-specific T cell–directly therapy.[101] The advantages of T cell–based therapies over antibody therapy is that EBV-specific T cell–immune reconstitution is restored, thus reducing the risk for disease recurrence. Responses to donor-derived EBV-specific T-cell therapies developed at multiple centers for pediatric patients range from 70% to 85%.[101,102] Immune-based therapies are generally preferred in this population since the use of chemotherapy in patients with LPD after HSCT is associated with high mortality rates secondary to increased infectious complications.[103] However, hydroxyurea and immune-based therapies may be an option for patients with CNS disease.[104] After solid organ transplant (SOT), modalities such as radiotherapy or surgical resection for localized LPD can result in complete remissions. One study evaluated the efficacy of low-dose cyclophosphamide and prednisone for pediatric patients with PTLD after SOT. All patients had progressed despite reduction of immune suppression and received six cycles of chemotherapy. The 2-year event-free and overall survival rates were 67% and 73%, respectively.[105] More recently, in a phase II study (COG-ANHL0221), the Children's Oncology Group evaluated the addition of the CD20 monoclonal antibody to the previously reported regimen of low-dose cyclophosphamide and prednisone, but the results are still pending (http://clinicaltrials.gov/show/NCT00066469). Finally, for patients refractory to these low-dose regimens or patients with definitive features of malignancy, standard lymphoma chemotherapy regimens are used depending on histologic subtype (e.g., BL versus DLBCL versus HL-directed therapy).

Hodgkin Lymphoma

Epidemiology

Hodgkin lymphoma (HL) accounts for 10% of all lymphomas and approximately 10% of pediatric cancers[2] and has a bimodal incidence, with one peak at 15 to 34 years of age and a second peak in the sixth decade. In children, the highest peak is among 15- to 19-year-olds (29 per million per year) and is least frequent in children under 5 years. There is an age-dependent sex predominance, with a male predominance in children under 5 years (male-to-female ratio of 5.3:1) and a slight female predominance in children ages 15 to 19 years (male-to-female ratio of 0.8:1). HL (especially the nodular sclerosing subtype) is classically associated with higher socioeconomic status, increased incidence in single-family homes, smaller family sizes, and a higher level of maternal education. In contrast, mixed-cellularity HL is inversely related to socioeconomic status. It is commonly postulated that delayed exposure to an environmental antigen may trigger development of HL, and higher rates of certain childhood infections (e.g., varicella, measles, mumps, rubella) are negatively associated with HL development.[106]

HL has been shown to have a genetic predisposition, although this is incompletely understood. Siblings of HL patients have a two- to ninefold increased risk for developing HL. There is also an increased risk among parent-child pairs, though not between spouses, supporting a genetic rather than a uniquely environmental predisposition. Environmental factors are nevertheless involved in HL. Approximately 40% of all HL cases in economically developed countries harbor EBV in the Hodgkin and Reed-Sternberg (HRS) cells. EBV positivity of the malignant HRS populations is more common in children under 10 years of age and is highly associated with childhood HL with mixed cellularity subtype (approximately 80% of cases) characteristically seen in developing countries. The EBV latent membrane protein 1 (LMP1) may be the key in the oncogenic process, since it can elicit B lymphocyte transformation in vitro.[107]

A relationship also exists between the development of Hodgkin lymphoma and cell-mediated immune deficiency with an increased incidence in patients with HIV and CVID. It remains unclear whether the underlying immune deficiency commonly seen in Hodgkin lymphoma is primary, secondary, or both.[107]

Pathobiology

Hodgkin lymphoma is generally considered to be slow growing with a tendency to spread to contiguous lymph nodes. Only in advanced stages is there evidence of blood vessel invasion and spreading to more distant organs.[108] Over the past 30 years, advances in the treatment of pediatric HL have been significant—over 85% of children are now cured with chemotherapy and/or radiation even with stage III/IV disease.

HL is notable for the characteristic B cell–derived HRS cells found in a background of an inflammatory microenvironment usually comprising Tregs, Th2 T cells, macrophages, and eosinophils. The REAL/WHO classification identifies two main subtypes: classical HL and lymphocyte predominant HL. Classical Hodgkin lymphoma accounts for the majority of cases in adolescents and young adults and is characterized by HRS cells, which are usually $CD15^+$ and $CD30^+$. HRS cells do not express B-cell markers such as CD19 and CD79A, although CD20 is expressed in approximately 5% to 10% of cases. Mixed-cellularity HL accounts for approximately one-third of cases diagnosed in children younger than 10 years. The histopathology shows frequent HRS cells on a background of normal reactive immune cells, including T lymphocytes, plasma cells, eosinophils, macrophages, and histiocytes. Lymphocyte-predominant HL and lymphocyte-rich classical HL may both have nodular appearances, but the former is more commonly CD15 negative and usually has strong CD20 and CD45 positivity, thus distinguishing it from classical Hodgkin lymphoma.[109]

Clinical Manifestations

The majority of pediatric patients with HL present with painless, firm, "rubbery" lymphadenopathy, most commonly in the cervical/supraclavicular regions. Over 70% of adolescents and young adults present with mediastinal disease, which can be asymptomatic. This presentation is less frequent in younger children and may be related to a lower incidence of nodular sclerosis HL and a greater frequency of mixed-cellularity or lymphocyte-predominant HL in this group. Approximately one-quarter of patients present with systemic "B"

symptoms including fevers, weight loss, and night sweats. The majority of pediatric patients presenting with HL have stage I, II, or III disease (involvement of lymph nodes and/or the spleen only) with a minority (approximately 15%) presenting with stage IV disease (noncontiguous extranodal involvement such as bone marrow, lung, liver, and/or bone).

Staging

Pediatric Hodgkin lymphoma is staged using the Ann Arbor staging system (with subsets A and B used for the absence or presence of B symptoms, respectively).[110] Briefly, stage I involves a single lymph node region. Stage II involves two or more lymph node regions on the same side of the diaphragm. Stage III involves lymph node regions above and below the diaphragm. For stages I to III, if extension to an adjacent extralymphatic region/organ is present, the designation E is added (e.g., stage IIE). Thus stage III HL with splenic involvement is designated stage IIIE. Finally, stage IV disease refers to multifocal, noncontiguous involvement of one or more extralymphatic organs or tissues, with or without involvement of associated lymph nodes. Isolated extralymphatic organ involvement with distant nodal involvement is also considered stage IV.

Treatment

Despite the excellent outcomes for children with HL, there is still no ideal therapeutic approach. Generally, combination chemotherapy with low-dose involved-field radiation is used with varying intensities and duration, usually depending on disease stage and prognostic factors such as disease bulk and B symptoms. However, studies of late effects in these patients[111] has fueled cooperative groups in particular to explore regimens with decreased radiation and/or chemotherapy doses, especially for children with low-risk disease. The general consensus, however, is that chemotherapy should be given to all HL patients, with or without radiation. The exception to this approach is patients with stage I, completely resected, nodular lymphocyte-predominant HL, who can achieve cure with surgery alone.[112]

Chemotherapeutic agents used for the initial treatment of pediatric HL are similar to those used for adults and include alkylating agents, steroids, vinca alkaloids, antimetabolites, doxorubicin, bleomycin, dacarbazine, and etoposide. However, doxorubicin (Adriamycin) is associated with cardiac toxicity, and bleomycin can lead to pulmonary fibrosis. Therefore many cooperative group studies have developed hybrid regimens using lower cumulative doses of alkylators, doxorubicin, and bleomycin especially for low-risk (stages I to IIA; no bulk; no B symptoms) and intermediate-risk (all stage I and II patients not classified as early stage; stage IIIA; stage IVA) disease. As shown in Table 83-8, the COPP/ABV (cyclophosphamide, vincristine (Oncovin), procarbazine, prednisone alternating with doxorubicin (Adriamycin), bleomycin, and vinblastine) regimen is one such example.[113] To preserve male fertility, etoposide has been substituted for procarbazine in the OEPA (vincristine [Oncovin], etoposide, prednisone, doxorubicin [Adriamycin]) studies developed by the German pediatric Hodgkin lymphoma group and dacarbazine for procarbazine in subsequent courses, resulting in an excellent EFS rate with no difference in outcome between boys and girls.[114] DBVE (doxorubicin, bleomycin, vincristine, and etoposide) and ABVE-PC (doxorubicin [Adriamycin], bleomycin, vincristine, and etoposide plus prednisone and cyclophosphamide) have been used in POG studies and, more recently, in COG trials.[115,116] Despite the inclusion of etoposide, the secondary leukemia rate appears very low in patients treated with DBVE or ABVE-PC without dexrazoxane.[115,116] Further, investigators from Stanford University Medical Center, Dana-Farber Cancer Institute, Massachusetts General Hospital, Barbara Bush Children's Hospital at Maine Medical Center, and St. Jude Children's Research Hospital have excellent results with low-risk disease with the VAMP regimen (vincristine, doxorubicin [Adriamycin], methotrexate, and prednisone)[117] (see Table 83-8).

Published clinical trial outcomes for low- and intermediate-risk pediatric HL patients (summarized in Table 83-8) have achieved 5-year EFS rates of 92% and 85%, respectively. For patients with high-risk disease (e.g., stages IIIB, IVB) POG used a risk-adapted approach with ABVE-PC plus low-dose involved field radiation therapy (LD-IFRT). Rapid early responders (RERs), defined by response on CT scanning after three ABVE-PC cycles, received 21 Gy involved-field radiation. Slow early responders (SERs) received two additional ABVE-PC cycles before radiation. For RERs the 5-year EFS was 86%, and for SERs, 83% ($P = 0.85$).[116] The Children's Cancer Group used intensive chemotherapy with cytarabine/etoposide, COPP/ABV or CHOP (2 cycles of either), plus or minus LD-IFRT. The 5-year EFS for stage IV patients was 90% for those who received RT and 80% for those who did not, leading to the

Table 83-8 Treatment Outcome for Low/Intermediate-Risk Pediatric Hodgkin Lymphoma

Study	*n* =	"Early Stage"	Prescribed Treatment	Cycles	Radiation	EFS

conclusion that RT should be given for these patients when used with this chemotherapy combination.[113] Finally, in the German GPOH-HD 95 trial, patients with stages IIEB, IIIEA, IIIB, or IV received six cycles OPPA (vincristine [Oncovin], prednisone, procarbazine, doxorubicin [Adriamycin]) for girls and six cycles OEPA for boys. Patients achieving complete remission (defined by CT scan) after chemotherapy were not irradiated, and all others received involved-field radiotherapy. In the high-risk groups however, the DFS was significantly worse for nonirradiated patients compared with patients who received RT (79% versus 91%), again confirming that with this regimen, radiation was needed for high-risk disease.[114]

Management of Relapsed Hodgkin Lymphoma

For patients who relapse, response depends on whether or not they had favorable disease at diagnosis and whether the relapse is confined to an area of initial involvement after chemotherapy and no radiation. These patients can generally be salvaged with chemotherapy and involved-field radiation therapy, and even without hematopoietic stem cell transplant, results are very acceptable. For all other patients, treatment of refractory, progressive, or relapsed disease includes induction chemotherapy with multiple chemotherapeutic agents not generally used in the initial therapy (e.g., gemcitabine, vinorelbine, carboplatin/cisplatin, ifosfamide, and more recently, brentuximab), followed by high-dose chemotherapy and autologous stem cell rescue. Conditioning regimens are generally alkylator based,[118] and the frequently reported regimens are CBV (cyclophosphamide, carmustine [BiCNU], and etoposide [VP-16]), BEAM (carmustine [BiCNU], etoposide, cytarabine [ara-C], and melphalan), and BEAC (carmustine [BiCNU], etoposide, cytarabine [ara-C], and cyclophosphamide).[119-121] None of these conditioning regimens produces a superior outcome in pediatric patients, and CVB and BEAM remain the most widely used. The role of local radiation therapy either before or after HSCT is still unclear, although TBI is now generally not used.[122,123] Although an overall DFS of approximately 50% is consistently reported with this approach, the reported range is 20% to 60% because outcomes are related to prognostic factors such as disease burden and chemosensitivity.[119,120,124,125]

The role of allogeneic HSCT has also been investigated for patients with relapsed/refractory HL, although never in a prospective, randomized manner.[126] The use of submyeloablative regimens (generally fludarabine based) may reduce transplant-related mortality rates while still achieving a graft-versus-lymphoma (GVL) effect in patients receiving allografts; this warrants further investigation in the pediatric population.[127,128] Finally, investigational therapies such as targeted T-cell therapies are being explored for pediatric HL patients with relapsed disease, either as adjuvant therapy after transplant or for relapsed disease.[129]

In summary, most children with HL are initially treated with risk-adapted chemotherapy alone or in combination with low-dose involved-field radiotherapy involving carefully designed radiation fields to achieve local disease control while minimizing bystander organ toxicity. Especially for low-risk patients, some studies suggest that the overall survival for patients receiving chemotherapy alone may be similar to that for patients receiving chemotherapy plus radiotherapy, despite possible differences in EFS. This is due to the fact that it is usually possible to salvage relapse after initial therapy.[114] If salvage therapy for such patients can be targeted and relatively nontoxic (e.g., using novel agents such as brentuximab),[130] then using a less-intense initial regimen may be appropriate. Currently, however, salvage therapy for the majority of patients is typically more toxic and can lead to an unacceptable incidence of late events such as cardiac toxicities and secondary malignancies.[131] Therefore strategies using a less-intense upfront regimen should be investigated only within the context of a clinical trial. Future clinical studies should attempt to address this important issue by evaluating the prognostic significance of achieving PET-negative disease after one or two cycles of chemotherapy and the use of upfront brentuximab to replace more toxic modalities such as bleomycin and radiation therapy.

Rare Subtypes of Lymphoma

Other subtypes that are observed rarely in children deserve mention, but the rarity of these neoplasms in children makes generalizations and therapeutic recommendations difficult. Follicular lymphomas (characterized by the arrangement of malignant cells in aggregates separated by normal cells), which account for approximately 30% of adult NHLs, are extremely rare in children. Children with follicular lymphomas tend to present with early-stage disease and cervical lymph node involvement (although primary tumors of the testis have been reported[132]) and have an excellent prognosis.[133] Unlike most cases of follicular lymphoma in adults, in which aberrant expression of BCL2, usually as a result of the t(14;18) translocation, is thought to play an important role in lymphomagenesis, the majority of cases of follicular lymphomas in children demonstrate neither the t(14;18) nor BCL2 expression. BCL2 expression appears to occur more frequently in older children and is associated with advanced-stage disease at presentation and a more aggressive clinical course.[133]

Marginal zone B cell lymphomas arising in mucosa-associated lymphoid tissue (MALT) can arise in extranodal sites. They tend to present with localized disease and infrequently disseminate. Natural killer cell lymphoma and NK-like T-cell lymphomas usually involve the upper aerodigestive tract (midline lethal granuloma, angiocentric T-cell lymphoma), but these can present in the skin as well. Such cases are rare in children and follow a very aggressive clinical course; these lymphomas are often fatal but may respond to high-dose chemotherapy with stem cell transplantation.[134] Peripheral T-cell lymphomas include a variety of neoplasms that have not yet been further specified. Although these lymphomas are rare in children, they generally present at advanced stage, often in association with systemic symptoms and hemophagocytic syndrome, and an aggressive course of treatment is the rule.

FUTURE DIRECTIONS

Although there have been dramatic improvements in the treatment of children with NHL and HL over the past 25 years, approximately 25% of children with these tumors still relapse or fail to respond to initial therapy. Additionally, late effects such as anthracycline-related cardiomyopathy, secondary malignancies such as epipodophyllotoxin-related acute myeloid leukemia, and endocrine abnormalities such as cyclophosphamide-related azoospermia remain a concern.[131,135] Thus a major task is to develop treatment strategies that provide a cure for the remaining 25% while also reducing treatment-related morbidity. Several approaches appear promising.

The identification of both clinical and biologic features at the time of diagnosis that predict treatment failure will enable investigators to refine existing risk-adapted therapeutic approaches. Strategies to be considered for children at high risk for treatment failure include the intensification of existing regimens and the incorporation of new active or novel agents. More-intensive therapy may require either autologous or allogeneic hematopoietic stem cell support. The administration of colony-stimulating factors may be necessary in some cases, although their role in therapy remains controversial. Novel approaches include the incorporation of immunotherapeutic agents into multiagent chemotherapy regimens. For example, there is increasing experience with the anti-CD20 antibody (rituximab) in pediatric patients with B-cell lymphomas.[56] A radiolabeled form of this product (yttrium-90 Zevalin) has also yielded promising preliminary results in children.[136] $CD30^+$ lymphomas, such as ALCL, mediastinal B-large cell lymphoma, and Hodgkin disease, are also candidates for CD30 antibody therapy. Novel immunotherapeutic approaches include the use of surface protein–specific cytotoxic T lymphocytes; this approach is effective in the prevention and treatment of EBV-related posttransplant lymphoproliferative disease, NHL and HL.[101,129] Agents targeting specific molecular lesions (e.g., the ALK inhibitor for ALCL) are promising and are already in phase I studies in children and the implementation of anti-idiotype and antisense strategies are also being studied.

The continued investigation of molecular abnormalities and pathogenic mechanisms of malignant transformation associated with childhood lymphomas is essential. Microchip gene arrays have already identified clinically relevant subtypes of large B-cell lymphomas in adults.[137] Gene array analyses of Burkitt lymphoma, anaplastic large cell lymphoma, and T-lymphoblastic disease have also been reported.[138] Similar studies are ongoing for childhood lymphomas and preliminary results for T-lymphoblastic leukemia/lymphoma have been published.[139] Comprehensive molecular characterization of childhood lymphomas may help to further refine disease classification, provide a means of detecting minimal residual disease (MRD) during clinical remission and enhance our assessment of early response.[140] Monitoring is facilitated by the finding that the level of MRD in the peripheral blood is comparable to that in the bone marrow in children presenting with advanced-stage lymphomas. Additionally, a more complete understanding of the molecular pathogenesis of pediatric HL and NHLs will provide clues to new and better treatments directed toward tumor-specific molecular lesions.

CHAPTER 84

T-CELL LYMPHOMAS

Owen A. O'Connor, Enrica Marchi, Govind Bhagat, Paolo Corradini, Joan Guitart, Steven T. Rosen, and Timothy M. Kuzel

The T-cell lymphomas are a heterogeneous group of diseases. They can be divided into those diseases that predominantly arise within the skin, and are thus referred to as the *cutaneous T-cell lymphomas* (CTCLs), and those that do not primarily arise in the skin, namely, the mature or peripheral T-cell lymphomas (PTCLs). Like the B-cell malignancies, each of these subcategories of T-cell lymphoma can be divided into indolent and aggressive diseases, each associated with its own treatment principles. Although CTCL is considered a mature T-cell lymphoma, these diseases are for the most part indolent in nature. They are characterized by a variety of clinical entities, each with its own unique biology and presentation. The mature or peripheral T-cell lymphomas typically arise in lymph nodes, extranodal sites, or as leukemic disease and are for the most part very aggressive diseases. The separation of the T-cell lymphomas into cutaneous or noncutaneous is largely intended to highlight some of the general differences in behavior, though clearly there is overlap. Some forms of CTCL can involve nodal and extranodal sites, and some forms of PTCL can involve the skin. Given the marked differences in biology, clinical behavior, and treatment of these two categories of T-cell lymphoma, this chapter has organized them into their own sections.

THE PERIPHERAL T-CELL LYMPHOMAS (NONCUTANEOUS)

The mature or peripheral T-cell lymphomas are a heterogeneous group of diseases. Similar to the B-cell neoplasms, there are some entities that are known to be relatively indolent, such as the CTCLs and CD30-positive anaplastic large cell lymphomas (ALCLs) of the skin. Most PTCL entities are, however, considered highly aggressive diseases that respond poorly to conventional chemotherapy. Among the most common subtypes are PTCL not otherwise specified (NOS), angioimmunoblastic lymphoma, angioimmunoblastic T-cell lymphoma (AITL), and the ALCLs. Although these diseases are considered to carry an unfavorable prognosis compared to their B-cell counterparts, select molecular entities, such as ALK-positive ALCL, are associated with a favorable prognosis, comparable to that seen with diffuse large B-cell lymphoma (DLBCL).

It is estimated that there were approximately 66,360 cases of non-Hodgkin lymphoma (NHL) in the United States in 2011, of which the T-cell lymphomas account for approximately 5% to 10% of all cases.[1] The median age at diagnosis is 59 years, which is slightly less than the median age of 66 for patients with NHL in general. Like other forms of lymphoma, the T-cell lymphomas are diseases of older adults, with approximately 40% of cases occurring between the ages of 55 and 74, and only about 5% of cases occurring after the age of 85. Between 2004 and 2008, Surveillance Epidemiology and End Results (SEER) reported the age-adjusted incidence rate of T-cell lymphoma as approximately 1.8 per 100,000 men and women. The incidence rates among all races in males and females is approximately 2.3 and 1.4 per 100,000 individuals, respectively, in contrast to 24 and 16.5 cases per 100,000 males and females for NHL. The disease is almost twice as frequent in males as females.[1] In general, the disease is far more common in Asia. For example, the International Peripheral T-Cell and Natural Killer/T-Cell Lymphoma Study noted that T-cell lymphomas accounted for only 5% to 10% of all NHL cases in Western countries and about 10% to 20% in Asian countries.[2] Rudiger et al[3] have reported that the frequency of PTCL in Vancouver, for example, was roughly 1.6%, compared to the 18.3% frequency in Hong Kong.

Although rare in the West, subtypes of PTCL are not uncommon in the Eastern hemisphere and in Central and South America. Geographic and ethnic variability have been cited as reasons for the differences in the prevalence of some types of PTCL. Exposure to certain infectious or environmental agents is thought to account for some of the geographic variation, especially with regard to human T-lymphotropic virus-1 (HTLV-1) infection and occurrence of adult T-cell leukemia/lymphoma (ATL), as well as Epstein-Barr virus (EBV) infection and the development of natural killer (NK)/T-cell lymphoma (NKTCL) in Asia, the Caribbean, and Central and South America. Globally the three most common subtypes of PTCL are PTCL-NOS (25.9%), AITL (18.5%), and ALCL (12%).[2] PTCL-NOS is recognized as being slightly more common in North America, with a lower incidence in Europe and Asia, whereas AITL is more common in Europe as compared to Asia or North America. Enteropathy-associated T-cell lymphoma (EATL) is associated with celiac disease (which itself is associated with leukocyte antigen DQ), which is more common in European populations.[4] Similarly, EBV-associated lymphomas are primarily seen in Japan, Korea, and northern China, as well as immigrant populations from South America in North America. These data suggest that there may be a variety of both genetic and environmental factors that may predispose to T-cell lymphomas, many of which are only now being identified in larger epidemiologic studies.

Classification

The classification of the PTCLs has evolved substantially over the past several decades. Older classification schemes failed to incorporate all the necessary immunophenotypic, cytogenetic, morphologic, and clinical data to subclassify these diseases, as now presented in the context of the World Health Organization (WHO) classification system. The most recent WHO classification published in 2008 recognizes more than 22 different subtypes of T-cell lymphoma distributed among four different subcategories. As shown in Table 84-1 and Fig. 84-1, these subcategories are divided into nodal, extranodal, cutaneous, and leukemic, each based on the predominant clinical behavior of that disease entity.

The nodal group consists of PTCL-NOS, which is the most common subtype of PTCL, accounting for roughly one-quarter of all PTCL cases. Other subtypes included ALCL and AITL. In ALCL there is a significant impact of specific cytogenetic features on prognosis. The ALK-positive forms of ALCL, which are characterized by the nucleophosmin (NPM)-ALK translocation [t(2;5)] have a highly favorable prognosis, whereas those variants that are ALK negative carry a relatively poor prognosis. Other than the presence of the ALK translocation as determined by fluorescence in situ hybridization (FISH), there is no way to differentiate these diseases on strictly morphologic or immunophenotypic grounds. As such, the appropriate therapeutic recommendations for these two diseases obligatorily involve an understanding of this specific cytogenetic feature. Each of

Table 84-1 WHO Classification of the Mature T-Cell Lymphomas

Leukemic	T-cell prolymphocytic leukemia T-cell large granular lymphocytic leukemia Aggressive NK-cell leukemia Indolent large granular NK-cell lymphoproliferative disorder (provisional) Adult T-cell leukemia (HTLV-1, ATL)
Extranodal	Extranodal NK/T-cell lymphoma, nasal type Enteropathy-associated T-cell lymphoma Hepatosplenic T-cell lymphoma Subcutaneous panniculitis-like T-cell lymphoma (αβ T-cell lineage only) Primary cutaneous γδ-T-cell lymphoma
Nodal	ALCL, systemic or cutaneous ALCL:ALK positive [t(2;5)] ALCL:ALK negative (provisional) PTCL-NOS
Cutaneous	Mycosis fungoides/Sézary syndrome Primary cutaneous $CD30^+$ T-cell LPD LYP and primary cutaneous ALCL Primary cutaneous $CD4^+$ small/medium T-cell lymphoma (provisional) Primary cutaneous $CD8^+$ aggressive epidermotropic cytoxic T-cell lymphoma (provisional)
Other	Systemic EBV-positive T-cell LPD of childhood Hydroa vacciniforme–like lymphoma

ALCL, Anaplastic large cell lymphoma; *ATL,* adult T-cell leukemia/lymphoma; *EBV,* Epstein-Barr virus; *HTLV-1,* human T-lymphotropic virus-1; LPD, lymphoproliferative disease; *LYP,* lymphomatoid papulosis; *NK,* natural killer; *NOS,* not otherwise specified; *PTCL,* peripheral T-cell lymphoma; *WHO,* World Health Organization.

these ALCL variants accounts for about 5% to 6% of all cases of PTCL. Similarly, it is often a significant diagnostic challenge to discriminate ALK-negative ALCL from PTCL-NOS. AITL is the second most common subtype of PTCL, accounting for about 18% to 19% of all cases of PTCL. It, uniquely, can also be associated with an EBV-infected clonal B-cell population.

The extranodal subtypes of PTCL are associated with their own unique clinical behavior. This subcategory can include very rare and aggressive diseases like hepatosplenic γδ-T-cell lymphoma. The γδ designation refers to the composition of dimeric protein that makes up the T-cell receptor (TCR). Approximately 95% of all PTCLs possess TCRs that carry the αβ-heterodimer, whereas the γδ-T-cell lymphomas, like hepatosplenic T-cell lymphoma, possess a TCR composed of the γδ-chains. The disease is thought to be derived from a highly primitive γδ-T-cell that has a penchant for infiltrating the liver and spleen. EATL accounts for less than 5% of all PTCL cases. EATL is highly associated with celiac disease, which itself is far more prevalent in Europe. As a result, EATL accounts for only about 6% of all PTCL cases in North America, about 10% in Europe, and less than 2% in Asia, where celiac disease is very uncommon. Panniculitis-like T-cell lymphoma is another subtype of extranodal PTCL. It accounts for less than 1% of all cases of PTCL and is associated with a very aggressive course and resistance to chemotherapy. The immunophenotype of the disease is usually CD3 and CD8 positive and CD4 negative. In addition, the disease can exhibit rearrangements in the TCR of the αβ or γδ variety. This rare form of lymphoma is often misdiagnosed, frequently being confused with the panniculitic-like lesions seen in lupus. It usually presents with subcutaneous nodules that may be necrotic, making rebiopsy the only avenue to diagnosis.

The leukemia subtypes of T-cell lymphoma largely consist of ATL, which is commonly associated with the HTLV-1 retrovirus. The immunophenotype is typically CD3 and CD5 positive, CD7 negative, with positivity for CD4 and CD25 in the majority of cases. ATL is associated with HTLV-1 infection in the clonal T-cell in 100% of cases. Typically the interval between viral infection and onset of lymphoma is long, on the order of 10 to 40 years, with usually less than 5% of infected individuals actually developing ATL. The disease is typically very aggressive, often involving the bone marrow and lymph nodes, though smoldering and chronic forms of ATL do exist and are often managed differently.

Pathobiology

The PTCLs comprise many rare subsets of NHLs that arise from postthymic T cells or NK cells, which can occur at nodal or extranodal sites. Over recent years there has been some progress in disease characterization and classification. Unlike B-NHLs, the pathogenesis of PTCL is poorly understood, and the cell of origin of many PTCL entities is unknown at present. Progress in understanding the etiology of PTCL and the associated pathogenetic molecular alterations is hampered by the rarity and heterogenous nature of this disease.

Anaplastic Large Cell Lymphoma

ALK-positive ALCL is one of the best characterized types of PTCL (Fig. 84-2). The chromosomal translocation t(2;5)(p23;q35) generates an NPM-ALK fusion protein leading to the constitutive activation of the ALK tyrosine kinase, which can be detected in 55% to 85% of systemic ALCL, with higher frequencies seen in children and young adults.[5,6] Alterations in multiple different signaling pathways have been described as a consequence of ALK translocations, which include the Janus-activated kinase 3 (JAK3)/signal transducer and activator of transcription (STAT3), phosphatidylinositol 3-kinase (PI3-kinase)/protein kinase (AKT)/mammalian target of rapamycin (mTOR), and the phospholipase C-γ (PLC-γ)–mediated Ras–extracellular signal-regulated kinase (ERK) pathways. In addition, abnormalities of CD30 signaling, MYC, and growth factor receptor–bound protein 2 (Grb2) (an adaptor protein) have also been reported.[5] A role for active Notch1 signaling has been proposed in ALK-positive ALCL, similar to that proposed in classic Hodgkin lymphoma (HL).[7] The cell of origin of ALK-positive ALCL has been debated. A cytotoxic T-cell origin has been proposed; however, there is speculation that the "null cell" phenotype could reflect a common end point for lymphomas arising from different T-cell subsets. Expression of Th17-associated molecules leading to the activation of a Th17 differentiation program has recently been reported for ALK-positive ALCL.[8]

Variant translocations involving ALK and other partner genes have been documented in a minority of cases.[5] Immunohistochemical staining for ALK can influence one's suspicion for such translocations, because an altered pattern of staining (cytoplasmic, membranous, or nucleolar instead of the nuclear and cytoplasmic) is observed depending on the ALK fusion partner (see Fig. 84-2). Pathologic consequences of the variant translocations are not adequately understood at present. The genetic basis for differences in the histopathologic subtypes of ALK-positive ALCL is similarly unclear. Differences in gene expression profiles between certain morphologic subtypes have been reported.[9] It is possible that these reflect differences in the tumor composition with regard to the admixture of nonneoplastic cells. Although molecular alterations associated with the different subtypes have not been well characterized, comparative genomic hybridization (CGH) array studies of NPM-ALK and variant ALK translocation–associated ALCL have reported similar recurrent secondary genetic abnormalities.[10] The genetic basis of aggressive disease in some patients with ALK-positive ALCL also remains to be elucidated. Of interest, secondary MYC translocations have been reported in some cases with adverse outcomes.[11,12]

ALK-negative ALCL shows morphologic and phenotypic similarity with ALK-positive ALCL; however, its histogenesis is not known at present. Array CGH analysis of ALK-positive and ALK-negative ALCL highlighted differences in secondary aberrations between the

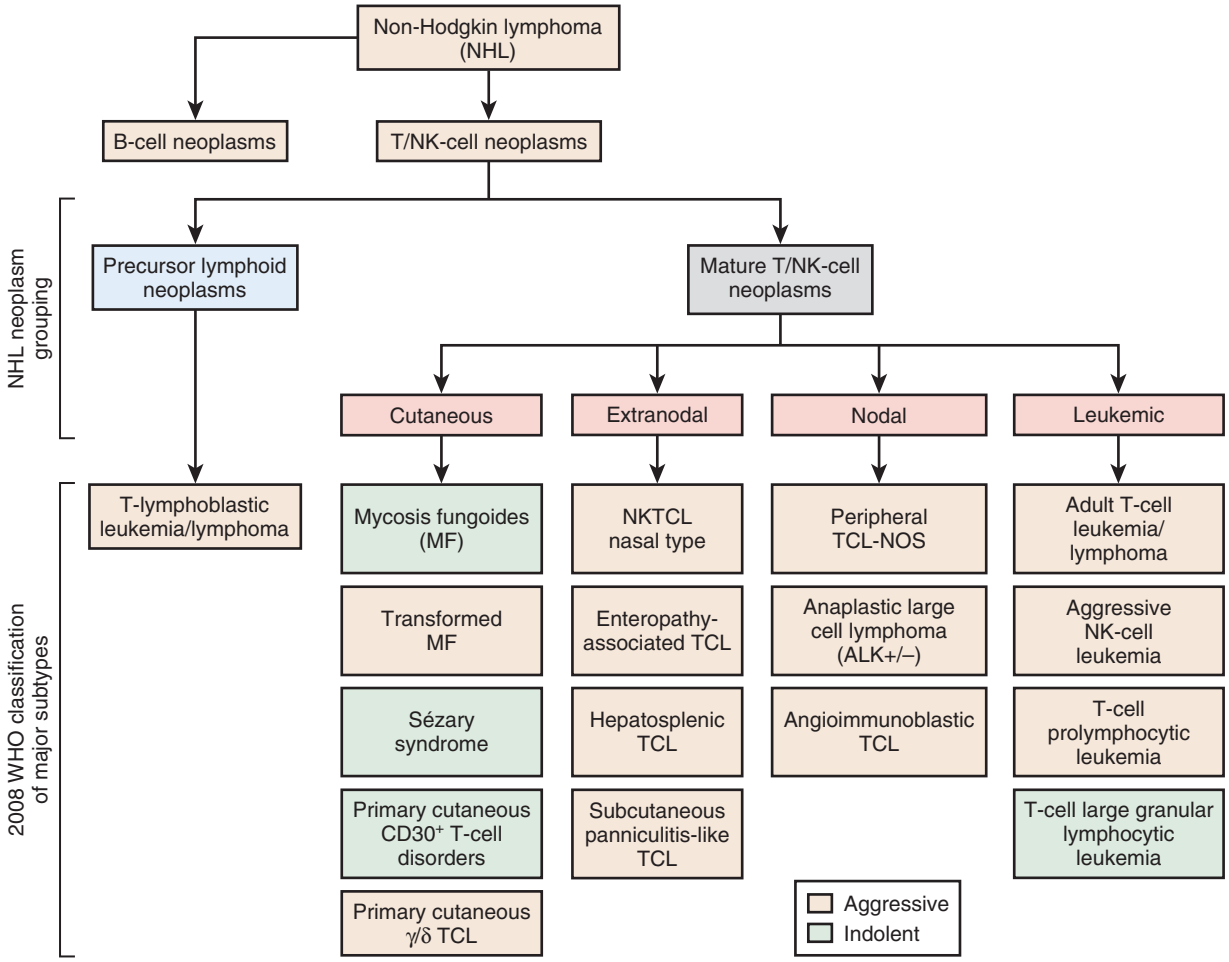

Figure 84-1 WHO CLASSIFICATION OF THE MATURE T-CELL NEOPLASMS. *NK,* Natural killer; *NOS,* not otherwise specified; *TCL,* T-cell lymphoma.

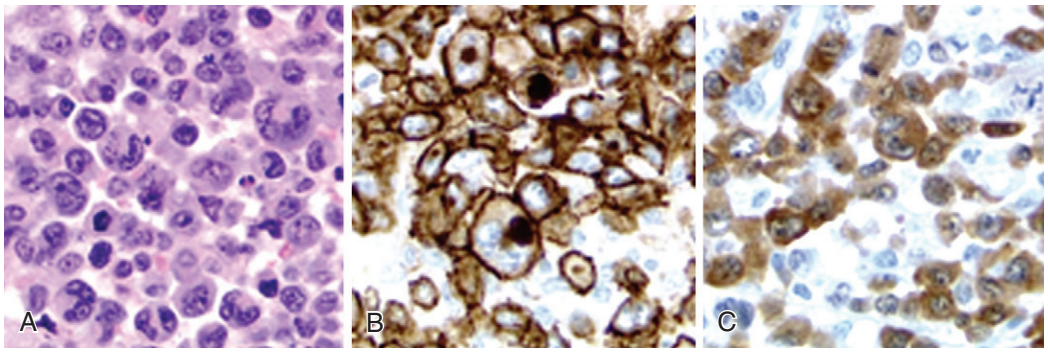

Figure 84-2 ANAPLASTIC LARGE CELL LYMPHOMA. Anaplastic large cell lymphoma has variable morphologic features but is typically composed of large, highly irregular "anaplastic" cells, which include giant cells sometimes with a wreath-like or horseshoe-shape nuclei, and "hallmark" cells, which are cells with a folded-up nucleus with an embryo shape **(A).** The cells are typically brightly CD30 positive **(B).** ALK1 staining with cytoplasmic and nuclear localization **(C)** is associated with the t(2;5)(p23;q35) translocation, whereas other patterns are associated with the variant translocations **(C).** Whether ALK1-negative cases should be considered as a separate group or classified together with peripheral T-cell lymphoma not otherwise specified is somewhat debatable (see text).

two subtypes.[10] Early analyses of gene expression profiles of ALK-positive and ALK-negative ALCL indicated deregulation of certain common kinase-signaling cascades and regulators of apoptosis.[13] ALK-positive and ALK-negative ALCL were shown to differ with regard to alterations in cell cycle regulators based on unsupervised analysis of expression profiles (overexpression of cyclin D3 in ALK-positive ALCL and underexpression of p19INK4D in ALK-negative ALCL). ALK-positive ALCL is associated with overexpressed genes encoding signal transduction molecules (Syk, Lyn, and Cdc37) and showed lower expression of transcription factors (HoxC6 or HoxA3) in comparison with ALK-negative ALCL.[13] Lamant et al,[9] using supervised analysis, described overexpression of BCL6, PTPN12, CEBPB, and SERPINA1, genes implicated in immune or inflammatory responses, regulation of the NF-κB signaling, and leukocyte

migration and adhesion, in ALK-positive compared to ALK-negative ALCL. The latter, on the other hand, could be distinguished by overexpression of cytokine-signaling pathway genes (CCR7, CNTFR, IL22, and IL21).

Peripheral T-Cell Lymphoma Not Otherwise Specified

PTCL-NOS is a clinically heterogeneous entity that comprises cases lacking morphologic and phenotypic features of other disease subtypes (Fig. 84-3). It is the most common subtype of PTCL, accounting for up to 25% of all PTCL cases worldwide. Using current histopathologic and immunophenotypic criteria distinguishing between PTCL-NOS and ALK-negative ALCL can be exceedingly difficult. This is mirrored at the chromosome level. Earlier studies analyzing G-band karyotypes could not determine any correlation between cytogenetic findings and histologic subtypes or clinical outcome.[14] PTCL-NOS and ALK-negative ALCL share karyotypic abnormalities, including gains of chromosomes 1q and 3p and losses of material on chromosome 6q, although the loci on 6q have been shown to differ.[15] Complex karyotypes have been associated with poor prognosis. Using higher-resolution approaches, such as CGH, overlapping aberrations, including 6q and 13q losses, have also been observed, but a few distinct aberrations were detected between the two entities.[16] Recurrent chromosome gains of 7q that target cyclin-dependent kinase 6[17] and 8q involving the MYC locus[18] have been reported in PTCL-NOS.

In 2006, Streubel et al[19] identified a recurrent translocation t(5;9)(q33;32) that resulted in the fusion of the interleukin 2 (IL-2) inducible T-cell kinase (ITK) gene with the spleen tyrosine kinase (Syk) gene in 17% of PTCL-NOS. Mouse models engineered to express the ITK-Syk fusion transcript develop T-cell lymphomas mimicking human disease.[20,21] Overexpression of Syk tyrosine kinase in the absence of Syk translocations with consequent Syk phosphorylation and activation has also been observed in PTCL.[22]

Earlier studies using expression profile analysis of limited numbers of genes failed to determine a distinct signature that could separate PTCL-NOS from other PTCL subtypes.[23] Analysis of a larger number of PTCL-NOS cases allowed segregation into two groups based on increased or decreased expression of NF-κB pathway genes, the latter associated with very poor survival. Ballester et al[24] were able to distinguish PTCL-NOS from other disease subtypes by gene expression profiling and further classify them into three subgroups based on alterations of different biologic processes or signaling pathways, some showing trends with better survival. Cuadros et al[25] identified a gene expression cluster for PTCL-NOS corresponding to 55 transcripts of proliferation- and cell cycle–associated genes, including CCNA, CCNB, TOP2A, and PCNA, which were all associated with a poor prognosis. Comparison of PTCL-NOS expression profiles with those obtained from purified different T-cell subsets demonstrated a relationship between PTCL-NOS with either activated $CD4^+$ or $CD8^+$ T cells. Deregulation of pathways controlling apoptosis, cell proliferation, adhesion, matrix remodeling, and chemoresistance could be discerned, and upregulation of platelet-derived growth factor receptor α was noted in many cases.[26] Derivation of PTCL-NOS from different cell types was also suggested by Iqbal et al,[8] who indicated a less favorable prognosis for a group that had signatures of cytotoxic T cells.

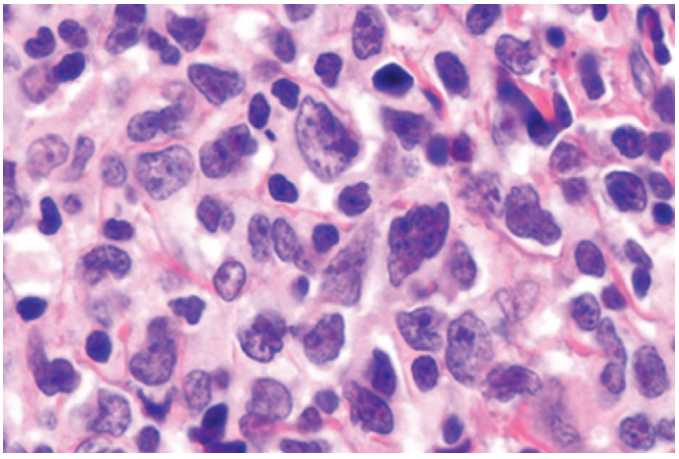

Figure 84-3 PERIPHERAL T-CELL LYMPHOMA NOT OTHERWISE SPECIFIED (PTCL-NOS). PTCL-NOS is morphologically heterogeneous. Typically, cases have a spectrum of small to large lymphoma cells, frequently with irregular nuclear borders and sometimes with clear cytoplasm. Other cases can have more of a predominance of small or large cells. Features of the other defined types of T-cell lymphoma should be lacking.

Angioimmunoblastic T-Cell Lymphoma

AITL was originally referred to as "angioimmunoblastic lymphadenopathy (AILD) with dysproteinemia" because it was considered to represent a state of deregulated immune response. Its categorization as a lymphoma was based on the detection of clonal TCR gene rearrangements (Fig. 84-4). Gains of chromosomes 3q, 5q, and 21 have been described as recurrent alterations, although the genes affected by these changes are not known.[15] Recent reports have described similarities between gene expression profiles of AITL and T-follicular helper (TFH) cells, with AITL overexpressing genes characteristic of

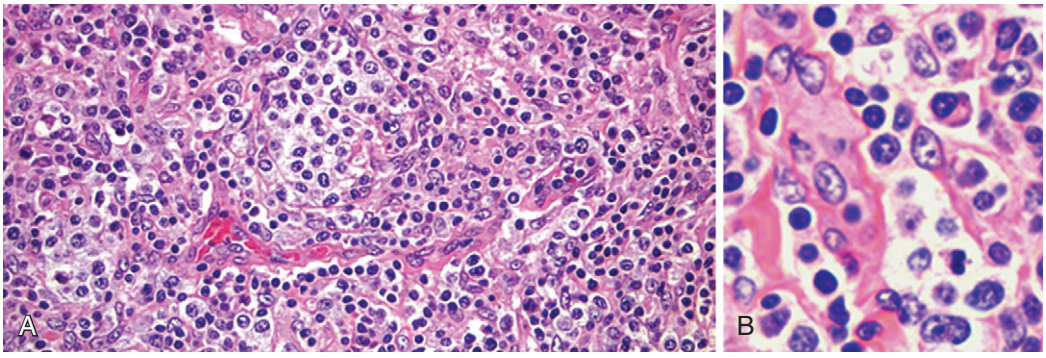

Figure 84-4 ANGIOIMMUNOBLASTIC T-CELL LYMPHOMA (AITL). A prominent feature of AITL is the prominent vasculature in the background. The vessels usually show branching and prominent endothelial cells **(A).** The cellular component is made up of a mix of plasma cells, immunoblasts, and small lymphocytes; the lymphoma cells can be of intermediate or large size and they tend to cluster and exhibit clear cytoplasm **(A, B).** Some cases can develop a superimposed Epstein-Barr virus–driven large B-cell lymphoma.

normal TFH cells (CXCL13, BCL6, PDCD1, CD40L, and NFATC1).[27] Numerous studies have confirmed the phenotypic profile of AITL to be similar to TFH cells.[28] A role for the tumor microenvironment has also been proposed in AITL pathogenesis.[8] Although vascular endothelial growth factor (VEGF) transcripts detected in AITL were originally thought to be derived from the vascular stroma of these neoplasms, expression of VEGF and its receptor (KDR) by the tumor cells was also demonstrated by Piccaluga et al.[29] It should be mentioned that recent immunophenotypic studies have also uncovered other types of PTCL with a TFH phenotype, including subsets of PTCL-NOS.[30] This might be one of the explanations for the inability of gene expression profiling to segregate AITL from subsets of PTCL-NOS in some instances.[29] Whether this indicates an origin of such PTCL from a TFH precursor or acquisition of a TFH phenotype due to derangement of transcriptional circuits remains to be seen. Genome-sequencing studies underway might establish developmental or mechanistic links between different PTCL subtypes. Such studies have already begun to provide insights into similarities and differences among PTCL subtypes. Quivoron et al[31] discovered an increase in T-cell progenitors and genesis of T-cell lymphomas in mice engineered to disrupt the function of the TET2 gene. On sequencing human lymphoma specimens, they found heterozygous insertions and deletions leading to TET2 frameshift and nonsense mutations in 33% of AITL and a smaller subset of other T-cell lymphomas. Other mutations, including those affecting the second allele, occurred later in lymphomagenesis. The same group then analyzed a large series of PTCL, including PTCL-NOS and AITL, and detected DNMT3A mutations in 73% of cases that had TET2 mutations (including both disease subtypes), suggesting possible oncogenic cooperation between TET2 and DNMT3A mutations and deregulation of cytosine methylation and demethylation processes in T-cell lymphomas.[32a] On screening a variety of PTCL subtypes for IDH1 and IDH2 mutations, Cairns et al[32b] detected heterozygous IDH2 mutations only in AITL (20% in a discovery set and 45% in a validation set), which resulted in an R172 substitution in the majority of cases. Unlike other neoplasms associated with IDH mutations, no IDH1 mutations were detected. The prognostic implications of this mutation, if any, are unclear at present. It also remains to be seen whether this mutation is specific for AITL or other subtypes of PTCL derived from TFH cells.

Natural Killer/T-Cell Lymphoma

NKTCL is associated with EBV infection, and episomal and/or viral integration into the deoxyribonucleic acid (DNA) of neoplastic T or NK cells can be detected (Fig. 84-5). However, other as yet–uncharacterized cooperating genetic and environmental agents likely also play roles in disease pathogenesis. Recurrent deletions of 6q21-25 were described in NKTCL by Wong et al.[33] Array CGH analysis of aggressive NK-cell leukemias and extranodal NKTCL, nasal type, has highlighted genomic differences between the two entities, with gains of 1q and losses of 7p15.1-p22.3 and 17p13.1 being detected more frequently in aggressive NK-cell leukemias, and gains of 2q and losses of 6q16.1-q27 and 11q22.3-q23.3, among others, being more commonly observed in NKTCL, nasal type.[34] A recent study incorporating gene expression analysis with array CGH mapped a novel tumor suppressor gene, HACE1, to the 6q21 region, but the role of this gene in disease pathogenesis remains to be defined.[35] These authors also reported overexpression of granzyme H and overexpression of PDGFRA in NKTCL similar to what has been described in PTCL-NOS. Amplifications of the C-REL gene have been detected in subsets of NKTCL.[36] More recently, deletions of two 6q21 regions detected in 36% of analyzed cases were further characterized by oligonucleotide array CGH and functional studies, which led to the identification of PRDM1 (BLIMP1) and FOX03 as novel tumor suppressors in NKTCL.[37] Rare PRDM1 mutations were also found. Küçük et al[38] confirmed a tumor suppressor role for PRDM1 and described monoallelic deletions and promoter hypermethylation of this gene in a significant percentage of NKTCT.

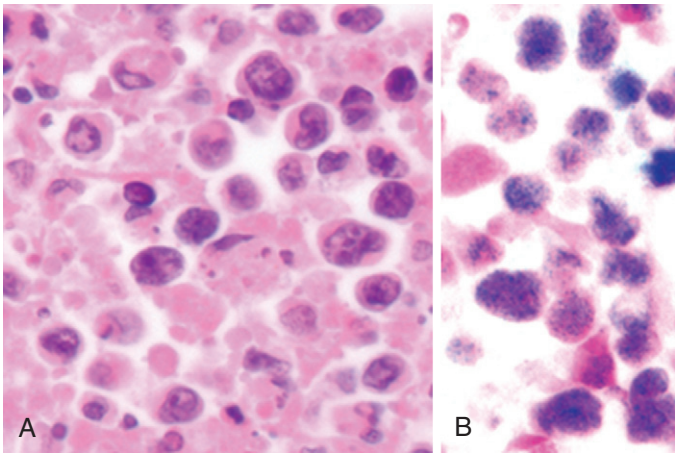

Figure 84-5 NATURAL KILLER (NK)/T-CELL LYMPHOMA, NASAL TYPE. The nasal type of NK/T-cell lymphoma **(A, B)** is usually associated with marked necrosis and karyorrhectic material indicating high cell turnover. The lymphoma cells are variable from case to case, but they invariably are Epstein-Barr virus (EBV) positive as demonstrated by in situ hybridization for EBV-encoded ribonucleic acid (RNA; **B**).

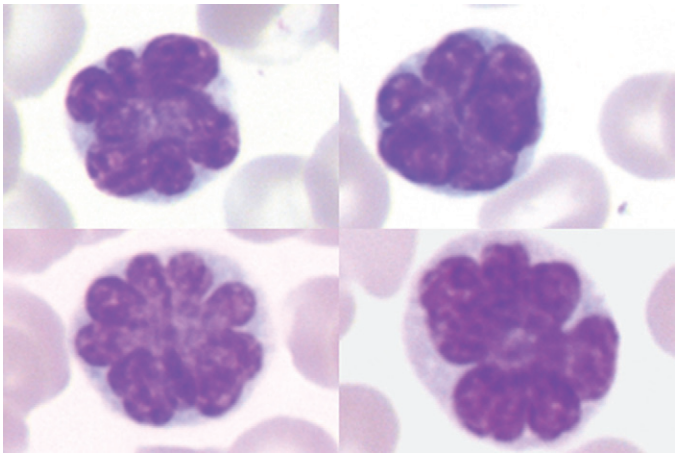

Figure 84-6 HUMAN T-LYMPHOTROPIC VIRUS-1–ASSOCIATED LEUKEMIA/LYMPHOMA. The leukemic process (adult T-cell leukemia/lymphoma) is characterized by circulating neoplastic T cells with a "flower-like" form. In some cases this cytologic feature is more prominent than in others.

Human T-lymphotropic Virus-1–Associated Acute T-Cell Leukemia/Lymphoma

HTLV-1 is a retrovirus that is transmitted via infected T cells present in body fluids, especially breast milk and semen, and blood of carriers of the HTLV-1 provirus. Clinicopathologic subsets of HTLV-1–associated lymphomas include acute ATL, smoldering ATL, lymphomatous ATL, and chronic ATL (Fig. 84-6). ATL is characterized by infection and clonal expansion of $CD4^+$ T cells in the vast majority of cases. Disease pathogenesis involves viral and host factors. A variety of viral proteins with transforming activity have been described, but the Tax protein is the best characterized. The NF-κB transcription factor is one of its targets.[39] Array CGH has highlighted differences in chromosomal alterations between subtypes and could provide hints regarding genes targeted by these alterations.[40] C-REL and IRF-4 expression has been associated with resistance of ATL to antiviral agents.[41]

Enteropathy-Associated T-Cell Lymphoma

EATL accounts for less than 5% of PTCL (Fig. 84-7). Currently, two types are recognized, EATL type 1 ($CD8^-$ and usually $CD56^-$) and type 2 ($CD8^+$ and often $CD56^+$). EATL type 1 is thought to arise from intraepithelial lymphocytes of the small bowel and is associated with celiac disease, occurring in individuals who carry human leukocyte antigen (HLA) DQ2 or DQ8 haplotypes, whereas EATL type 2 is unrelated to celiac disease. Refractory celiac disease (RCD) type II is considered a precursor of EATL, and approximately 50% of individuals with RCD type II develop EATL within 5 years.[42] There are little data regarding genetic abnormalities in RCD type II; however, recurrent gains at chromosome 1q22-q44 have been reported in one study.[43]

Genomic analyses of EATL type 1 have revealed recurrent gains and losses of chromosomal regions that might contain potential oncogenes and tumor suppressor genes. Using microsatellite markers, Baumgartner et al[44] detected frequent amplifications of 9q34 (40%) and slightly less frequent recurrent gains at 5q33.3-34 and 7q31 in EATL. Analysis of these patterns suggested two different disease types, one characterized by gains of 9q34 and another exhibiting allelic imbalances at 3q27.[44] A role for amplification of Notch1 and ABL1 genes, located on chromosome 9q, has been proposed as possible pathogenetic aberrations in EATL.[44,45a] Using CGH, Zettl et al[45b] confirmed the high frequency of 9q gains in EATL (58%) and further refined the minimal region of aberration as 9q33-q34. Recurrent gains at 7q, 5q, and 1q and losses of 8p, 9p, and 13q have been described in these lymphomas. Deleeuw et al,[46] using whole genome tiling array–based CGH, identified genomic abnormalities underlying both types of EATL. Complex chromosomal gains of 9q were seen in 70% of cases and virtually mutually exclusive losses of 16q21.1 in 30% of cases. Of note, gains of 1q and 5q were more frequently observed in EATL type 1, while gains of the MYC locus (8q24) were detected more often in EATL type 2. Segmental amplifications of the 9q31.3-qter chromosomal region or deletions in 16q12.1 were seen in both types of EATL. Recent array CGH analysis of Asian EATL type 2 also detected a high frequency of 9q33-q34.1 gains (80% of cases), suggesting similarities with cases occurring in the West, and documented other recurrent alterations, including gains of 6p21.1-21.31 and 19q, and losses of 3p12.1-p12.2 and 3q26.31.[47] Gene expression analysis of these lymphomas has not yet been performed to determine alterations of any particular signaling, survival, or metabolic pathway.

Hepatosplenic T-Cell Lymphoma

Hepatosplenic TCL is a rare PTCL, which has been associated with underlying immune dysfunction (Fig. 84-8). It is most commonly of γδ-T-cell lineage; however, lymphomas bearing the αβ-TCR have been described, as have occasional cases lacking surface TCR. Isochromosome 7q [i(7)(q10)] is reported to be a frequent recurrent chromosomal aberration, but specific abnormalities of particular genes have not been defined.[48] Of interest, i(7)(q10) has been detected in hepatosplenic T-cell lymphoma irrespective of the phenotype (γδ or αβ). Moreover, an increase in the number of 7q signals was detected in some cases that had features of cytologic progression, suggesting a tendency of the neoplastic cells to increase the dosage of the i(7)(q10) as the disease evolves.[49] Miyazaki et al,[50] using unsupervised analysis of gene expression profiles, were able to classify hepatosplenic γδ-TCL as a distinct cluster but were not able to discriminate between other types of γδ-TCL and αβ-TCL. This could

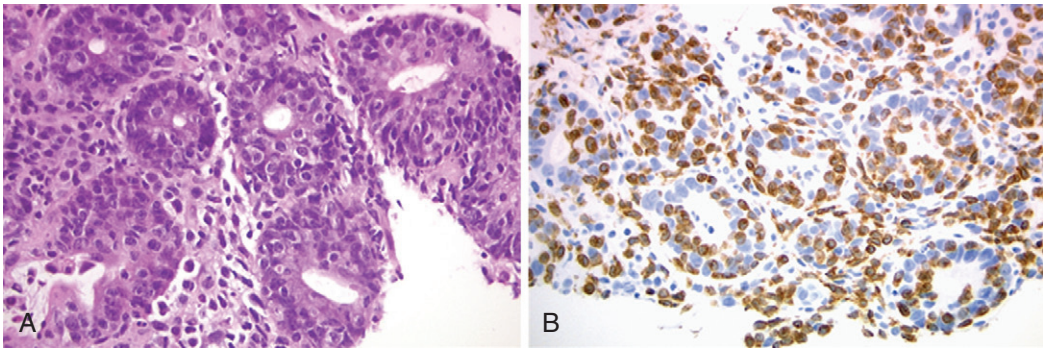

Figure 84-7 ENTEROPATHY-ASSOCIATED T-CELL LYMPHOMA. In enteropathy-associated T-cell lymphoma there is prominent infiltration of gastrointestinal glandular elements by neoplastic T cells **(A).** These are typically $CD3^+$ **(B)** and almost always $CD5^-$ and $CD4^-$ negative, and CD8, and CD56 variable, depending on the type.

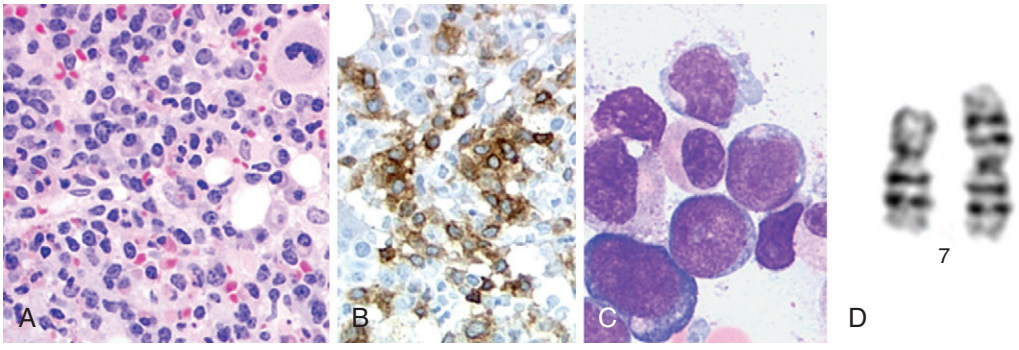

Figure 84-8 HEPATOSPLENIC T-CELL LYMPHOMA. Hepatosplenic γδ-T-cell lymphoma is commonly diagnosed from a bone marrow biopsy specimen in a patient being evaluated for hepatosplenomegaly. The bone marrow typically shows a subtle lymphoid infiltrate **(A),** which becomes more evident with a T-cell stain such as CD3 **(B).** This highlights the classic sinusoidal distribution of the lymphoma. Lymphoma cells may be seen in the circulation or in the marrow aspirate and can resemble monocytes or blasts **(C).** The lymphoma is typically associated with isochromosome 7q, as illustrated in the partial karyotype **(D).**

be due to part of the signature being derived from splenic tissue. Of interest, the authors were able to discern overexpression of NK cell–associated transcripts, such as killer-cell immunoglobulin (Ig)-like receptor (KIR) genes and killer lectin-like receptors.

Clinical Manifestations

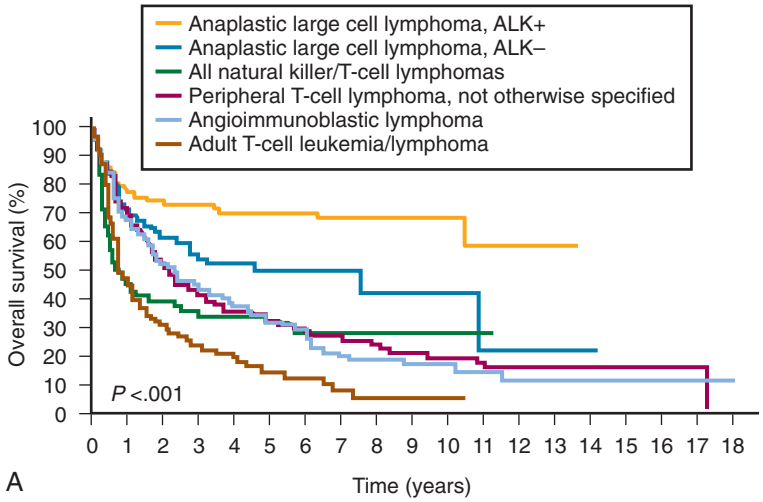
PTCLs, with the exclusion of CTCL, recapitulate the general presentation of aggressive NHL, which can vary depending on histologic features, patient age, and immune status. PTCL generally presents with lymphadenopathy, and patients can range from being asymptomatic to presenting with serious organ compromise. PTCL can present as nodal, extranodal, leukemic, and cutaneous disease, which are discussed separately. An extranodal presentation is common in PTCL and often contributes to a delay in the diagnosis. When compared to aggressive B-cell lymphomas, patients with PTCL tend to present with more advanced disease, a poorer performance status, and frequently B symptoms. Patients may have constitutional manifestations because of the production of inflammatory molecules and a variety of other cytokines and chemokines produced by the lymphoma cells and host tissues. Paraneoplastic features, including eosinophilia, hemophagocytic syndrome, and autoimmune phenomena, have been well described in different PTCL subtypes. For example, the AITL is often characterized by systemic symptoms, skin rash, organomegaly, hypergammaglobulinemia, and hemolytic anemia. It affects older adults, and patients frequently present with peripheral lymphadenopathy, hepatosplenomegaly, skin rash, and constitutional symptoms. By contrast, hepatosplenic T-cell lymphoma, which often occurs in young adults, is characterized by marked hepatosplenomegaly and bone marrow involvement.

Laboratory Manifestations

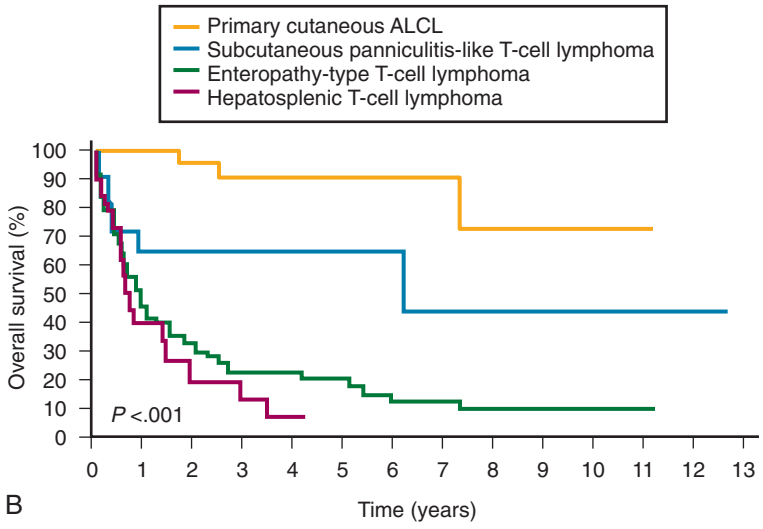
Laboratory tests should include a complete blood count, serum chemistry determination (including lactate dehydrogenase [LDH]), human immunodeficiency virus status, and other viral studies, including HTLV-1 status and EBV in appropriate cases. The level of β_2-microglobulin is usually normal compared to that found with the B-cell lymphomas.

Differential Diagnosis

Accuracy in diagnosis of the PTCLs more often than not requires the consensus of hematopathologists with a specific expertise in this field. Diagnosis is based on examination of peripheral blood or tissue biopsy specimen for histologic features supplemented by detailed immunohistochemistry, flow cytometry, cytogenetics, and molecular genetics. Expert hematopathologic review is essential for the correct classification of the different subtypes, given the often poor concordance among hematopathologists in matching the diagnosis. Detailed clinical information is obviously important in making the correct diagnosis. For example, in patients from Japan, information regarding HTLV-1 status is essential to aiding the pathologist in distinguishing between lymph node involvement due to PTCL-NOS and ATL. Because this disease also occurs in the West, HTLV-1 status should be evaluated in patients at high risk for the disease or from endemic areas. Other diagnoses such as AITL and EATL are often clarified by the clinical information. For cases in which it is difficult to distinguish between different entities, gene expression profiling may become helpful in the future for confirming the correct diagnosis.



Prognostic Factors



The majority of PTCLs are associated with a very poor prognosis as compared to their B-cell counterparts[2] (Fig. 84-9). Treatment outcomes for PTCL patients are substantially inferior to those for their B-cell lymphoma counterparts. Lymphomas derived from the T-cell lineage have been shown to be an independent negative prognostic factor.[51] The International Peripheral T-Cell and Natural Killer/T-Cell Lymphoma study reported that the overall survival (OS) and failure-free survival (FFS) at 10 to 15 years was only 10%. The International Prognostic Index (IPI), which is based on age, performance status, LDH level, stage, and extranodal involvement, appears to be useful in determining the prognosis for certain PTCL subtypes. However, even patients in the best risk categories (IPI 0 or 1) do not have a favorable outcome, and patients in the high-risk categories have a very short survival. When compared to the IPI curves seen for patients with B-cell lymphoma, the curves seen for patients with T-cell lymphoma essentially identify two risk categories, those with IPI 0 or 1 having a relatively more favorable outcome and those with IPI 2 or higher with an unfavorable outcome. In contrast to what is seen in patients with B-cell lymphoma, there is limited separation of the curves. When analyzed as a function of the histopathologic subset, the 5-year OS for patients with PTCL-NOS and AITL with IPI 0 or 1 was only 56% and 50%, respectively, whereas for those patients with IPI 4 or 5 it was 11% and 25%, respectively. Among patients with ALCL, the 5-year survival for IPI 0 or 1 is roughly 90% and 74% for the ALK-positive and ALK-negative patients, respectively. Patients with IPI 2 or higher have a poor outcome, with 5-year survivals of only 33% and 13% in the ALK-positive and ALK-negative populations, respectively. These observations confirm that IPI is an important predictor even in ALK-positive ALCL. The IPI has been less useful in stratifying patients with other subtypes of PTCL, including those with ATL, EATL, hepatosplenic T-cell lymphoma, or extranasal NKTCL.

Other prognostic models have been developed specifically for patients with PTCL. The Prognostic Index for PTCL (PIT) was developed based on risk factors that include age, LDH level, performance status, and bone marrow involvement. When applied to a PTCL-NOS population, the PIT stratified patients into more distinct prognostic groups compared to the IPI. Of 322 patients studied, 20% had no adverse features, 34% had one, and 20% had three or more. The 5-year OS for the most favorable subgroup with no adverse prognostic features was 62% compared to 18% for patients with three or four prognostic factors.[52] Despite improved stratification, the so-called favorable-risk population of patients with PTCL still had a strikingly poor outcome.

Efforts to improve on the more traditional clinically-based scoring systems have been proposed. The Bologna scoring system[53] was developed integrating both patient-specific and tumor-specific characteristics (age >60 years, performance status, LDH level, and Ki-67 protein ≥80%), stratifying patients into low-risk (score 1), intermediate-risk (score 2), and high-risk disease (score 3), with median overall survivals of 37, 23, and 6 months, respectively. Although the scores seem to be able to stratify the patient population, it is clear that there is no really favorable population of patients. The prognostic capability of the Bologna score was validated by Briones et al.[54]

Recently the International Peripheral Lymphoma Study (IPLS) showed that the 5-year OS of 340 patients with PTCL-NOS was only 32% (after 3 years' follow-up), whereas the 5-year FFS was only 20%[55,56] (Fig. 84-10). In this analysis, each of the prognostic factors in the IPI was a highly significant predictor of OS and FFS ($P < .001$; Fig. 84-11). The overall IPI was predictive of both OS and FFS, whereas the PIT was predictive of only survival. Bone marrow involvement was not a robust predictor of OS ($P = .03$) or FFS ($P = .06$) (Fig. 84-12). The PIT did not prove to be superior to the IPI in predicting the survival of patients with PTCL-NOS. Only one group with relatively good FFS was identified using both models. The IPLS evaluated other potential predictive factors by univariate analysis, establishing that the following factors were adverse prognostic factors of OS and FFS, respectively: B symptoms ($P = .004$; $P = .014$), bulky disease greater than or equal to 10 cm ($P = .005$; $P = .004$), elevated serum C-reactive protein level ($P = .018$; $P = .008$), circulating tumor cells ($P < .001$; $P < .001$), and a platelet count of less than 150×10^9/L ($P < .001$; $P < .001$). For unclear reasons, hypergammaglobulinemia fell out as a favorable prognostic

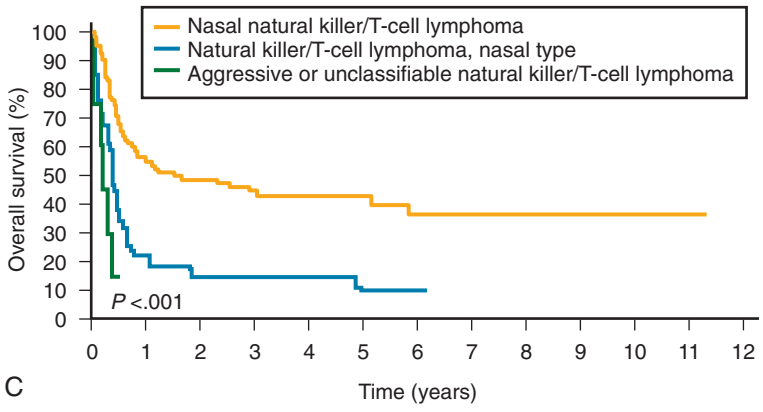


Figure 84-9 A, Overall survival of patients with the common subtypes of peripheral T-cell lymphoma (PTCL). **B,** Overall survival of patients with less-common subtypes of PTCL. **C,** Overall survival of patients with natural killer/T-cell lymphoma. *(Data from Vose J, Armitage J, Weisenburger D: International peripheral T-cell and natural killer/T-cell lymphoma study: Pathology findings and clinical outcomes.* J Clin Oncol *26:4124, 2008.)*

factor for OS and FFS ($P = .04$; $P = .03$). When the data were analyzed in a multivariate analysis, after controlling for IPI, only bulky disease greater than or equal to 10 cm was still predictive of survival with a hazard ratio (HR) of 2.1 for OS ($P = .019$) and 2.5 for FFS ($P = .003$), whereas a platelet count of less than 150×10^9/L was predictive of FFS (HR = 1.6, $P = .016$).

The IPLS also explored the impact of several pathologic features that were associated with inferior OS and FFS, including the following: Ki-67 index more than 25%, the presence of transformed tumor cells more than 70%, significant numbers of EBV-positive B cells (Epstein-Barr encoded ribonucleic acid [EBER] 3-4$^+$), and CD56 and CD30 expression by more than 20% on tumor cells. EBV positivity was predictive of an adverse survival only in patients younger than 60 years and was independent of a history of immunosuppressive therapy or autoimmune disorders. Factors that appeared to be favorably associated with improved OS and FFS included lymphoepithelioid (Lennert) variant and background CD8$^+$ T cells constituting more than 10% of the population. Several clinicopathologic factors were identified to be of prognostic significance by univariate analysis, but only bulky disease (>10 cm) and thrombocytopenia ($<150 \times 10^9$ cells/L) were predictive of OS.

Probably the most important prognostic factor for any subtype of PTCL is the presence or absence of ALK in ALCL. The OS of ALK-positive ALCL is substantially better than that seen for ALK-negative

ALCL (71% ± 6% versus 15% ± 11%, respectively). However, within the good prognostic category of ALK-positive ALCL, survival was 94% ± 5% for the low/low-intermediate risk group (age-adjusted IPI 0 to 1) and 41% ± 12% for the high/high-intermediate risk group (age-adjusted IPI ≥2). Multivariate analysis identified ALK expression and the IPI as independent variables that were able to predict survival among T/null primary, systemic ALCL.[56]

More recently, recognizing the biologic and clinical heterogeneity of PTCL, investigators have begun to develop subtype-specific prognostic models. Although potentially interesting, these models still need to be validated in large studies.

Therapy

Standard of Care

CHOP-Like Therapy in Mature T-Cell Lymphomas

The treatment for the PTCLs has largely mirrored the strategies employed for the treatment of DLBCL. Consequently, CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone) has emerged as the "standard of care" despite disappointing outcomes. The milestone SWOG trial that compared CHOP

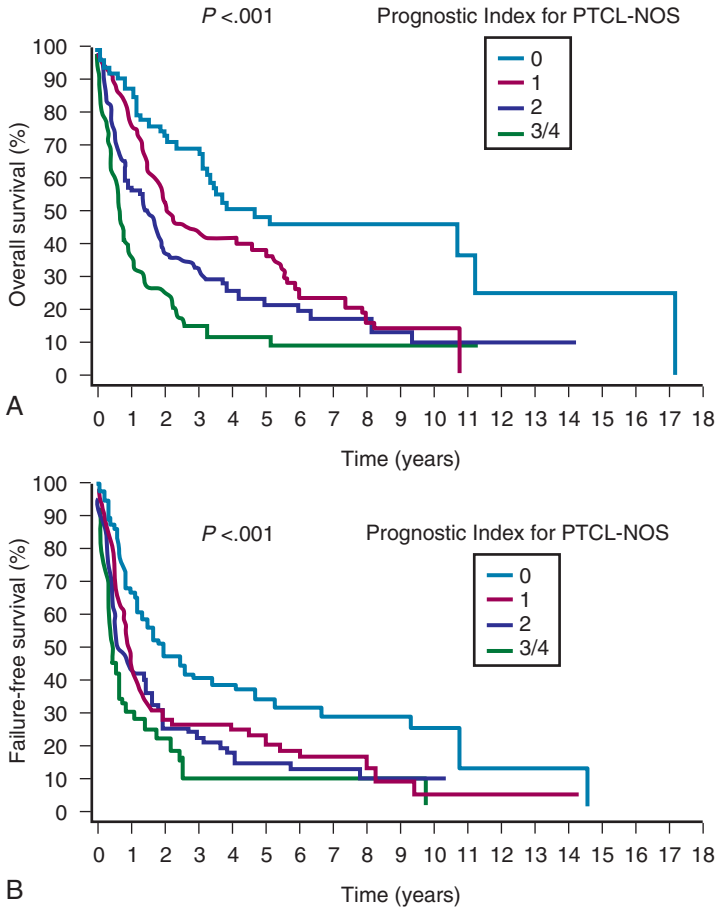

Figure 84-12 OVERALL SURVIVAL **(A)** AND FAILURE-FREE SURVIVAL **(B)** OF 315 PATIENTS WITH PTCL-NOS ACCORDING TO THE PROGNOSTIC INDEX. *PTCL-NOS,* Peripheral T-cell lymphoma not otherwise specified. *(Data from Weisenburger DD, Savage KJ, Harris NL, et al: Peripheral T-cell lymphoma, not otherwise specified: A report of 340 cases from the International Peripheral T-cell Lymphoma Project.* Blood *117:3402, 2011.)*

with the second- and third-generation dose-intensive regimens in aggressive lymphoma established that CHOP exhibited the same efficacy and less toxicity than the other regimens.[57] This landmark trial was based on the use of a histopathologic classification system when immunophenotyping was not yet routinely applied to all cases. Unfortunately, there are no large randomized prospective studies that compare the benefit of anthracycline-based therapies to other combination regimens in PTCL.

Conventional chemotherapy such as CHOP has led to disappointing results in patients with T-cell lymphomas. When the main subgroups of T-cell lymphomas were analyzed, only ALCL with the t(2;5) translocation (NPM-ALK fusion protein) had an equivalent or superior prognosis compared to patients with DLBCL.[51,56] The LNH87 study conducted by the Groupe d'Etudes des Lymphomes de l'Adulte showed that the use of anthracycline-containing chemotherapy regimens in T- and B-cell lymphomas were able to induce the complete remission (CR) in 54% versus 63% of the patients, with an OS of 41% and 53% and an event-free survival (EFS) of 33% and 42%, respectively.[51] The same group published the results of the LNH84 study, in which they employed a dose-intense consolidation. Again, although there was no difference in the response rate, patients with T-cell lymphomas relapsed more frequently and earlier as compared to patients with B-cell lymphoma.[58] More recently the CHOEP regimen (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], etoposide, and prednisone) was retrospectively studied by the German High-Grade Non-Hodgkin Lymphoma Study Group in 343 patients with T-cell lymphoma, including PTCL-NOS, ALCL, and AITL, who had been included in seven German high-grade phase 2 or phase 3 aggressive NHL treatment studies. The main purpose was to determine whether the addition of etoposide or shortening of the interval of chemotherapy from 3 weeks to 2 weeks affected survival.[59] In older adult patients, neither shortening the interval nor the addition of etoposide improved the EFS and OS.

A recent literature review and metaanalysis[60] reported a CR rate of 52% achieved with CHOP/CHOP-like regimens (excluding ALK-positive ALCL), with an estimated 5-year OS of only 35% in PTCL. This is in contrast to the 65% or better long-term survival frequently reported in DLBCL. Select studies reporting on the activity of various combination regimens in PTCL are presented in Table 84-2.

Anaplastic Large Cell Lymphoma

ALCL is a unique subtype of an aggressive mature T-cell lymphoma that carries a highly favorable prognosis, especially for patients with IPI 1 or 2 disease. Virtually all cases of ALCL express CD30, and about half of the patients with this disease harbor the t(2;5)(p21;q35) translocation. This chromosomal aberration leads to fusion of the NPM gene with the ALK tyrosine kinase, leading to its constitutive activation. As discussed earlier, the presence of the ALK translocation confers a highly favorable prognosis, and determination of the ALK status by FISH is imperative in all cases of ALCL, especially those in which the differential diagnosis also includes PTCL-NOS. The National Comprehensive Cancer Network guidelines recommend standard CHOP-based chemotherapy for these patients, sometimes combined with radiation for bulky disease, leading to remission rates close to 80%. Patients who experience relapse of their disease typically exhibit the same poor prognosis as patients with other subtypes of PTCL. Patients with ALK-negative ALCL carry the same poor prognosis as other subtypes of mature T-cell lymphoma and may be suitable candidates for clinical trials in both the up-front and relapsed settings.

Nasal NKTCL—Combined-Modality Versus Single-Modality Approaches

Radiotherapy is considered the most active treatment for early-stage nasal NKTCL.[61] For patients with limited stage IE or stage IE disease without any adverse factors, radiotherapy alone should be pursued with curative intent.[62] For patients with extensive stage I and II disease, radiotherapy followed by consolidation with chemotherapy is commonly used. Because of the intrinsic drug resistance frequently seen in this disease, chemotherapy is not recommended as primary treatment in early-stage nasal NKTCL. Extranodal NKTCL is generally refractory to CHOP-based chemotherapy and is often associated with the expression of the multidrug resistance genes.[61]

Despite the benefit of radiotherapy in this disease, a uniformly accepted standard of care has yet to be identified. Recently a phase I/II study using concurrent chemotherapy and radiotherapy was reported.[63] Patients were treated concurrently with radiotherapy and chemotherapy, which included carboplatin, etoposide, ifosfamide, and dexamethasone. Among the 26 patients reported, the objective response rate (ORR) was 81% with 77% CR. The most common grade 3 nonhematologic toxicity was mucositis (30% of patients), which was related to the radiotherapy. With a median follow-up of 32 months, the study reported a 2-year OS of 78%, which compares very favorably with the historical control group, which received radiotherapy alone (45%). Increasingly, many physicians are considering combined-modality therapy as the best up-front treatment for this disease, despite the potentially significant associated toxicity.

Newer approaches for patients with advanced NKTCLs have explored integrating L-asparaginase into a dexamethasone (steroid), methotrexate, ifosfamide, and etoposide–based backbone (SMILE). Yong et al[64] treated 18 patients that were refractory to CHOP with L-asparaginase, vincristine, dexamethasone, and involved field radiotherapy. The ORR was 83.3%, with 10 (55.6%) of the patients achieving CR, and five (27.8%) achieving partial response (PR). The 5-year overall survival rate was 55.6%. Results of the preliminary clinical study indicated that the L-asparaginase-based salvage regimens significantly improved the response rate and 5-year survival rate. A prospective phase II trial has been reported with the SMILE regimen in patients with newly diagnosed stage IV or relapsed refractory NKTCLs.[65] Among the 39 patients treated, 29 (74%) completed the planned treatment. The responses included 15 patients in CR and 14 in PR, with early deaths due to infection in 4 patients. Infection was the most commonly observed toxicity, seen in 41% of the patients. Based on these studies, we conclude that L-asparaginase may have a role, either in the up-front setting or for patients with relapsed or refractory disease.

Adult T-Cell Leukemia/Lymphoma—Role of Antiviral Agents

In patients with ATL the results of chemotherapy have been uniformly poor, leading to a consensus recommendation to enroll patients when possible in a clinical trial in either the up-front or relapsed or refractory setting. Although there is again no standard of care for these patients, the general sentiment is that CHOP-based chemotherapy regimens are insufficient. Owing to the comparatively higher incidence of ATL in Japan, many studies regarding the management of ATL come from Asia. The Japanese evaluated a complex combination regimen of VCAP (vincristine, cyclophosphamide, doxorubicin [Adriamycin], and prednisone), AMP (doxorubicin [Adriamycin], ranimustine [MCNU], and prednisone), and VECP (vindesine, etoposide, carboplatin, and prednisone) against CHOP-14 in ATL.[66] A total of 118 patients were enrolled in the trial and treated with either six courses of VCAP-AMP-VECP every 4 weeks or eight courses of biweekly CHOP. The CR rate was higher in the VCAP-AMP-VECP arm than in the CHOP-14 arm (40% versus 25%, respectively), and the progression-free survival (PFS) at 1 year was 28% in the VCAP-AMP-VECP arm compared to 16% in the CHOP arm. The OS at 3 years was 24% in the VCAP-AMP-VECP arm and 13% in the CHOP arm. Overall, the toxicity in the VCAP-AMP-VECP arm was higher than in the CHOP-14 arm, with substantially more grade 3 or 4 cytopenias in the VCAP-AMP-VECP arm, which included three toxic deaths. Because most patients with ATL do not have curable disease when treated with these chemotherapy regimens, it is reasonable to consider allogeneic stem cell transplantation (SCT) in patients who show responses to chemotherapy. Although this experience is very limited, there is some suggestion that there may be benefit in some patients.[67]

Infection with HTLV-1 can cause ATL. Nineteen patients with acute or lymphomatous forms of ATL were treated with oral zidovudine (200 mg five times daily) and interferon-α (Intron A; 5 to 10 million units subcutaneously each day). Seven of these patients either relapsed or were refractory to combination chemotherapy. Major responses were achieved in 58% of the patients (11 of 19), including complete remission in 26% (5 of 19). Four patients in whom prior cytotoxic therapy had failed experienced major responses, two of which were complete remissions. Six patients have survived for more than 12 months, with the longest remission since the discontinuation of treatment lasting more than 59 months.[68] A recent metaanalysis evaluated 116 patients with acute ATL, 18 patients with chronic ATL, 11 patients with smoldering ATL, and 100 patients with ATL lymphoma.[69] The 5-year OS rates were 46% for 75 patients who received first-line antiviral therapy ($P = .004$), 20% for the 77 patients who received first-line chemotherapy, and 12% for the 55 patients who received first-line chemotherapy followed by antiviral therapy. The metaanalysis suggested that patients with acute, chronic, and smoldering ATL significantly benefited from first-line antiviral therapy, whereas patients with ATL lymphoma experienced a better outcome with chemotherapy. In acute ATL, 82% of patients were alive at 5 years with antiviral therapy, and 100% of patients with chronic and smoldering ATL were alive at 5 years. Multivariate analysis showed that first-line antiviral therapy significantly improved OS (HR = 0.47; 95% confidence interval [CI], 0.27 to 0.83; $P = .021$). Prospective studies are warranted to better define the role of antiviral therapy in treatment of ATL.

Angioimmunoblastic T-Cell Lymphoma—The Role of Cyclosporin and Rituximab

AITL is one of the most common forms of PTCL with peculiar clinical and pathologic features. Although the normal counterpart has been recently identified as the TFH) cell, the nonneoplastic cells typically represent the quantitatively major component of AITL. Clinically the manifestations of the disease reflect a dysregulated immune and/or inflammatory response rather than being the direct complication of tumor growth,[70] supporting the concept of a paraneoplastic immunologic dysfunction. Despite the use of different intensive anthracycline-based chemotherapies, AITL is an aggressive disease compared to other PTCLs, for which the optimal therapeutic strategy is still not defined. Given the considerable immune dysregulation present in AITL, the possible role of cyclosporine A (CsA) has been investigated.[71] Twelve patients were treated with CsA; 10 out of 12 patients had failed prior therapy with either chemotherapy and/or steroids (one to two prior regimens). Two patients were untreated because of age or comorbid conditions. Three patients achieved CR and five a PR for an overall response rate of 67%, suggesting a possible role for CsA in this setting. In AITL, symptoms linked to B-lymphocyte activation are common, and variable numbers of $CD20^+$ large B-blasts, often infected by EBV virus, are found in the neoplastic tissues. It has recently been investigated that the disruption of putative B- and T-cell interactions and/or depletion of the EBV reservoir by anti-CD20 monoclonal antibody (rituximab) might improve clinical outcome observed with conventional chemotherapy. Twenty-five newly diagnosed patients were treated in a phase II study with eight cycles of rituximab plus chemotherapy (R-CHOP21). The complete response rate was 44%, the 2-year PFS rate was 42%, and OS was 62%. This trial showed no clear benefit of adding rituximab to conventional chemotherapy[72] (see box on Treatment of Peripheral T-Cell Lymphoma).

Treatment of Peripheral T-Cell Lymphoma

Given that the mature T-cell lymphomas are relatively rare diseases, there is a lack of large randomized clinical trials comparing the "standard" CHOP and CHOP-like regimens to other more-intensified chemotherapy strategies, or even other novel drug platforms. Our approach involves tailoring the treatment to the specific histologic subtype and age of the patient. From the outset, we send HLA typing for possible allogeneic stem cell transplant, assuming the patient is eligible, and request immunohistochemical staining of the primary tissue for CD30. Where possible, we preferentially try to put all patients on a clinical trial. For the majority of peripheral T-cell lymphomas, our standard initial approach is to use an etoposide-based regimen (CHOEP or EPOCH), especially for young patients or older adult patients with an excellent performance status. As alluded to earlier, there are some data to suggest a reduced failure-free interval and higher complete response rate. For patients with a poor performance status or older adult patients, standard CHOP administered on an every-21-day basis for six to eight cycles would be our preferred recommendation. In select cases, where an older adult patient is not a candidate for combination chemotherapy and requires palliative care, we have successfully used single-agent gemcitabine to obtain disease control and improve performance status. Those patients who attain a complete remission are usually referred for an autologous stem cell transplant. Those patients who do not attain a complete remission with standard frontline chemotherapy are typically referred for treatment with one of the drugs recently approved by the FDA for patients with relapsed or refractory disease, including pralatrexate, romidepsin, or brentuximab vedotin (if $CD30^+$ positive). For patients who relapse or are refractory to frontline and beyond therapy, we typically consider allogeneic stem cell transplant, assuming they are transplant eligible and have an appropriate HLA match.

Role of Stem Cell Transplantation in Treatment

Because of the poor results often seen with conventional chemotherapy in patients with PTCL, many investigators have begun to explore intensive treatments, including high-dose chemotherapy followed by autologous or allogeneic SCT in both a frontline therapy and in patients who have relapsed. Despite the growing number of reports, one must keep in mind a series of limitations: (1) most of the studies are retrospective; (2) randomized trials between standard chemotherapy and SCT have not been published so far; (3) many prospective studies of autologous SCT (ASCT) include both first-line and relapsed patients with diverse subtypes of T-cell lymphoma, making the results very heterogeneous and difficult to interpret.

High-Dose Chemotherapy and Autologous Stem Cell Transplantation

High-dose chemotherapy followed by ASCT is currently accepted as the treatment of choice for patients with relapsed aggressive B-cell lymphoma, resulting in 40% to 50% long-term disease-free survival, as demonstrated by the pivotal PARMA study.[73] The role of ASCT in TCL is less clear, and the burning issue is whether or not autografting during first or subsequent remissions may be of clinical benefit.

The Spanish Lymphoma/Autologous Bone Marrow Transplant Study Group (GELTAMO) reported the results of 123 patients with high-risk PTCL who received an ASCT in the salvage setting: the 5-year OS and PFS were 45% and 34%, respectively. In this analysis, having more than one factor of the adjusted-IPI or a high β_2-microglobulin level at transplant was identified as adverse prognostic factors.[74] Moreover, PFS and OS of patients in second or subsequent CR at transplant (35% and 57%, respectively) were superior as compared to those in more than a second PR (23% and 33%) or with refractory disease (10% and 9%). Other groups have underscored the importance of being in CR at the time of transplant to achieve a long-term survival.[75] This is not surprising and is a recurring theme in many transplant studies.

Some studies have focused on the different results between PTCL-NOS and ALCL, emphasizing that the histologic subtype can influence the outcome after ASCT.[76-79] The Toronto group compared relapsed and refractory PTCL patients with those affected by DLBCL, who were transplanted for the same indications over the same period. The 3-year OS and EFS were 48% and 37%, respectively, for PTCL, compared to 53% and 42% for DLBCL.[76,77] Nevertheless, a significantly different outcome has been demonstrated when the major subtypes of PTCL were analyzed separately. Patients with PTCL-NOS had an inferior EFS (3-year EFS, 23%) when compared to patients with DLBCL. In contrast, patients with ALCL exhibited a similar outcome to patients with DLBCL. These results are consistent with the data from a retrospective study of the Memorial Sloan-Kettering Cancer Center that reported a 5-year PFS of 24% for relapsed or refractory ALK-negative ALCL.[77] The more favorable prognosis of ALCL after ASCT was confirmed also by studies from Northern Europe investigators.[78,79]

Overall the prognosis of ALK-negative PTCL seems poor when ASCT is used for relapsed disease, where long-term remissions have been observed in less than one-third of the patients. Those who benefited the most are the patients with ALK-positive ALCL in CR at the time of transplant or those with a low IPI. Based upon the poor results of both front-line standard chemotherapy and ASCT in the salvage setting, high-dose chemotherapy has been investigated as first-line treatment.[80-84,85b] Although there are no randomized prospective trials comparing frontline ASCT with standard chemotherapy, the results of some retrospective and prospective phase II studies are suggesting a role for this approach (Table 84-3). In a retrospective analysis, the Japan registry demonstrated that the long-term outcome of PTCL was better in patients transplanted in first CR or PR than those not in remission (5-year OS, 72.9% versus 45.8%; PFS, 73.1% versus 42.2%).[80] The British Society of Bone Marrow Transplantation (BSBMT) and Stanford University reported similar data. The 2-year OS and PFS were 62% and 59%, respectively, for patients receiving ASCT as consolidation during first CR.[81,86] The Spanish group published a retrospective analysis of 74 patients undergoing SCT after the achievement of CR with first-line anthracycline-based induction chemotherapy.[82] After a median follow-up of 67 months, 5-year OS and PFS were 68% and 63%, respectively, and the main cause of death was disease progression. In multivariate analysis only the PIT score was significantly associated with OS and PFS. Although data about ALK expression were lacking, patients affected by ALCL had a significantly better outcome as compared to other PTCL subtypes. The same authors published the results of a prospective study in 26 high-risk nodal PTCL patients, excluding those with ALK-positive ALCL.[87] The patients who were positron emission tomography–positive after three cycles of dose-escalated CHOP (MegaCHOP) received salvage chemotherapy followed by autologous transplant. At a median follow-up of 35 months, 3-year OS and PFS of the entire cohort of patients were 73% and 56%, respectively, whereas those patients who were rescued by high-dose chemotherapy achieved a 2-year disease-free survival of 63%.

An Italian multicenter prospective study employed high-dose sequential chemotherapy followed by ASCT as first-line treatment in 62 patients with high-risk PTCL (stage III-IV and/or age-adjusted IPI >1) including 19 ALK-positive ALCL patients.[83] On an intent-to-treat analysis, only 46 of 62 patients (74%) completed the whole

program. Progressive disease during the induction phase was the main obstacle for proceeding to ASCT and the main reason for treatment failure. The high progression rate led to disappointing 12-year OS and EFS curves (34% and 30%, respectively). However, in the cohort of patients who underwent ASCT, the response rate was high: 89% of these patients achieved CR. As in the Spanish study, patients with ALCL had the most favorable OS and EFS (62% and 54%, respectively, compared to 21% and 18% of non-ALCL). On the other hand, when patients with PTCL-NOS were in CR at the time of transplant, the EFS was 62% versus 10% for those not in CR. The CR status remained a significant predictor of long-term outcome in the multivariate analysis.

More recently the German group published the results of a prospective multicenter study employing myeloablative doses of cyclophosphamide and total body irradiation as the conditioning regimen for 83 ALK-negative ALCL patients who were at least in partial remission after six CHOP cycles.[84] Similar to the Italian data, 34% of the patients did not complete the study protocol because of progressive disease. The estimated 3-year OS was 71% for patients who underwent ASCT compared to 11% for those who did not.

To increase the number of patients undergoing ASCT in complete or at least partial remission, some recent trials were designed that focused on a more intense pretransplant phase. The Nordic Lymphoma Group included a dose-dense induction phase for 160 PTCL patients. After six cycles of CHOEP every 2 weeks, 85% of the patients achieved CR and 70% could undergo ASCT at the last follow-up. Five-year OS and PFS were 50% and 43%, respectively. A Spanish group used alternating CHOP and ESHAP (etoposide, methylprednisolone [Solu-Medrol], cytarabine [ara-C], cisplatin) in the induction phase of 41 ALK-negative patients: 58% of the patients were in CR or PR after the induction phase, but only 41% of them underwent ASCT.[85b]

From the studies reported above, two important messages emerge clearly: (1) one of the reasons for treatment failure is disease progression before ASCT, therefore the intent-to-treat analyses give unsatisfactory PFS and OS curves; (2) for the two-thirds of the patients who are able to undergo the ASCT as frontline therapy, the results, especially for patients in CR before transplant, appear better as compared to those observed with patients receiving an ASCT after relapse.

Although most of the published data include different histologic subtypes of T-cell NHL, during recent years some efforts have been made to define the role of ASCT in specific subtypes. AITL patients have a median survival of 18 months after conventional chemotherapy, with less than 50% of the patients achieving CR. A retrospective analysis of the European Group for Blood and Marrow Transplantation in 146 AITL patients demonstrated an OS and PFS of 59% and 42%, respectively, at 4 years.[88] The PFS was greater in patients who received ASCT in CR, 56% at 4 years, compared to 23% in the case of patients with chemotherapy-refractory disease. EATL is another very poor-prognosis PTCL, commonly associated with celiac disease. Because of its rarity, very few data on EATL treatment are available. In a prospective observational study using ASCT as first-line treatment, 5-year OS was 60% versus 22% for patients treated with standard chemotherapy.[89]

In conclusion, the role of ASCT in T-cell NHL may be summarized as follows: (1) ALK-positive ALCLs have a favorable outcome after ASCT, but they also do well with conventional chemotherapy, allowing this strategy to be possibly delayed to the salvage setting; (2) patients affected by PTCL seem to have an advantage when transplanted in first CR; (3) in order to validate the results in larger cohorts of patients and with longer follow-up, all PTCL patients should be enrolled in prospective trials including ASCT as first-line treatment; (4) clinical protocols should be designed with an innovative pretransplant phase in order to achieve the best disease response before transplant and increase the number of patients who are able to get an ASCT. Novel agents might be useful to induce a response in patients having refractory disease before SCT.

Even in the absence of randomized trials, the current standard of care is the use of ASCT for young patients frontline.

Allogeneic Stem Cell Transplantation

Allogeneic SCT has been generally used in T-cell lymphomas with progressive or refractory disease after several lines of chemotherapy or in case of relapse after an autologous transplant. This strategy can provide the infusion of lymphoma-free graft and the potentially active graft-versus-lymphoma effect. The survival after myeloablative allogeneic SCT has been heavily influenced by the high nonrelapse mortality (NRM), mainly related to graft-versus-host disease, infections, and acute organ toxicities. Retrospective comparative analyses of autologous versus allogeneic SCT in aggressive lymphomas presented some selection bias because patients receiving allogeneic SCT usually had more advanced disease, more prior therapies, and/or bone marrow involvement.[90] However, these studies demonstrated that allogeneic SCT induced a lower relapse risk compared to ASCT, but the high NRM offset any survival benefit. The results of some studies using allogeneic SCT as therapeutic strategy are listed in Table 84-4.

A small retrospective comparative study by the GELTAMO group evaluated the outcome of patients receiving autologous (n = 29) or allogeneic SCT (n = 7) for PTCL. The 3-year OS was 39% and 29% for autologous and allogeneic SCT, respectively. However, the majority of patients in the group receiving allogeneic grafts in CR died because of transplant-related complications.[91] In 2006 a Japanese group published the first large analysis on the outcome of T-cell NHL after myeloablative allogeneic SCT from matched related and unrelated donors.[92] Fifty-one patients were retrospectively described, and, in univariate analysis, OS was better for PTCL compared to B-cell NHL or other T-cell NHL.

During the last 15 years, reduced-intensity conditioning (RIC) regimens have been increasingly used in relapsed lymphomas in order to reduce the NRM, thus making this strategy feasible in older adult or heavily pretreated patients.[93] In 2004 one of the first papers of RIC allogeneic SCT reported 56% of patients alive and in complete remission after 1.4 years.[94] The first prospective study evaluated the outcome of 17 relapsed PTCL patients after a fludarabine-based RIC regimen: 14 of 17 enrolled patients were alive (12 in CR) after a median follow-up of 28 months with an estimated 3-year NRM, OS, and PFS of 6%, 81%, and 64%, respectively.[95] In this study, there were some data suggesting the existence of a graft-versus-T-cell lymphoma effect, based on the following observations: (1) the achievement of durable responses with allogeneic SCT in patients who had already failed a previous ASCT and (2) the demonstration of clinical responses to donor lymphocyte infusions. These preliminary results were then supported by a larger Italian multicenter retrospective study with a longer follow-up. In this study, the 5-year outcome showed an NRM, OS, and PFS of 12%, 50%, and 40%, respectively, and a plateau in the survival curves after 36 months, suggesting that these patients have been cured by allogeneic SCT.[96] Following multivariate analyses, age over 45 years and refractory disease were independent prognostic factors, highlighting that the timing of allogeneic SCT can significantly influence the final clinical outcome. Similarly, in a French retrospective study of 77 PTCL patients receiving allogeneic SCT with both RIC or myeloablative regimens, those patients with chemosensitive disease or with less than two prior lines of chemotherapy experienced a better outcome.[97] In both the Italian and French studies, the survival was not significantly different among the

histologic subtypes of T-cell lymphoma (of note, the majority of ALCLs had an unknown ALK mutational status), although AITL did slightly better. In support of this finding, a European Group for Blood and Marrow Transplantation retrospective analysis on 45 AITL patients undergoing an allogeneic SCT between 1998 and 2005 showed a relapse risk of 20% at 3 years with a PFS of 53% and an OS of 64%.[98]

In the last few years a growing number of retrospective and prospective studies have demonstrated the feasibility and efficacy of allogeneic SCT in relapsed and refractory T-cell NHL, including the extranodal subtypes.[99-102]

In conclusion, allogeneic SCT can be offered in relapsed and refractory T-cell NHL based on the following observations: (1) in all studies the survival curves seem to reach a plateau after 24 to 36 months, suggesting the potential curability of the disease; (2) delaying allogeneic SCT too long from diagnosis may significantly impair the results, thus allogeneic SCT should be performed during a chemosensitive relapse; (3) RIC regimens have increased the feasibility of allogeneic SCT by reducing the NRM and may be used, at least in older and heavily pretreated patients. The future will hopefully see the combination of new agents with allogeneic SCT to improve the results in the significant proportion of refractory patients.

Emerging New Drugs for PTCL

There is little question that one of the most promising new areas in PTCL research is new drug development. Over the past several years, three new drugs, all with relatively unique mechanisms of action, have been approved for the treatment of patients with relapsed or refractory disease. These drugs, which all now have substantial data demonstrating their marked single-agent activity in these diseases, have created a unique opportunity to build non–CHOP-based platforms for treatment. In addition to the three drugs already approved, many new drugs are in various stages of clinical development, with very promising signals (Table 84-5). We will discuss some of these new agents and how they are beginning to change the treatment paradigms for PTCL.

Pralatrexate

Pralatrexate is a novel antifolate with very high affinity for the reduced folate carrier. The reduced folate carrier is an oncofetal protein expressed at relatively high levels on the surface of malignant cells.[103] The carrier is responsible for transporting into the cell natural folate required for DNA biosynthesis. Pralatrexate, designed to have a high affinity for the folate receptors, is rapidly internalized into the cell, where it undergoes efficient polyglutamylation by the folylpolyglutamate synthase, which enhances the affinity of the drug for dihydrofolate reductase and increases its intracellular retention.[104]

A phase "II-I-II" study of pralatrexate in patients with relapsed or refractory NHL established the maximum tolerated dose as 30 mg/m^2 weekly for 6 of 7 consecutive weeks of treatment.[105] The dose-limiting toxicity was determined to be mucositis, which was largely controlled with the addition of folic acid and vitamin B_{12}. These data revealed an ORR of 31% among the entire population of patients with both B- and T-cell lymphoma (n = 48 evaluable), of which 8 patients obtained a CR. Among the 20 evaluable patients with B-cell lymphoma, the ORR was 5%, of which there were no CRs. Among the 26 evaluable patients with T-cell lymphoma, the ORR was 54%, of which there were 8 CRs.[105] All the complete remissions, many of which were very durable and included patients who had responded to prior methotrexate, were seen exclusively in patients with PTCL.

These data gave rise to a pivotal study of pralatrexate in patients with most subtypes of relapsed or refractory PTCL. The Pralatrexate in Patients With Relapsed or Refractory Peripheral T-Cell Lymphoma (PROPEL) study was an international, open-label, single-arm trial in which pralatrexate was administered at a dose of 30 mg/m^2 weekly for 6 of 7 consecutive weeks. At the time, it was the largest study ever conducted in this patient population. Of 115 patients enrolled, 111 were treated with pralatrexate.[106] Overall, the patient population was very heavily pretreated, with the median number of prior therapies being 3, with a range of 1 to 12. Twenty percent of patients in PROPEL had received more than five lines of prior chemotherapy. The response rate among the 109 evaluable patients was 29%, which included 12 CRs (11%), with a median duration of response of 10.1 months. The most common grade 3 or 4 toxicities included

Table 84-5 Recent FDA-Approved and Emerging New Drugs in Peripheral T-Cell Lymphoma

Drug	Disease/No. of Patients	Overall Response Rate	Complete Response Rate	PFS/DOR	Reference

thrombocytopenia and mucositis. These data led to pralatrexate becoming the first drug ever approved by the U.S. Food and Drug Administration (FDA) for PTCL, receiving accelerated approval in late 2009.

More recently, pralatrexate has been reported to potently synergize with gemcitabine,[107] bortezomib,[108] and the histone deacetylase (HDAC) inhibitor depsipeptide.[109] These data have now led to a number of phase I clinical trials exploring the merits of these drug combinations.

Histone Deacetylase Inhibitors

The HDAC inhibitors (HDACI) appear to exhibit a consistent pattern of activity in T-cell neoplasms, with little to no activity in B-cell lymphoid malignancies. HDACs play a crucial role in modulating the balance between open and closed chromatin, which in turn modulates transcriptional activation. Histone acetyltransferases acetylate the ε-amino moieties of lysine residues found both in histone and nonhistone protein. Acetylation of histone proteins facilitates an open chromatin structure, leading to access by transcription factors and thus transcriptional activation. Conversely, HDACs facilitate deacetylation of chromatin, which leads to a closed chromatin structure and transcriptional silencing. Although the modulation of chromatin structure has been long postulated as one of the key mechanisms for HDACI activity, it is now widely recognized that these drugs are more appropriately recognized as more general protein deacetylase inhibitors. In this capacity, it is also recognized that HDACI may functionally affect tumor cell growth and survival by modulating the posttranslational state of different proteins, which leads to activation or inactivation of various tumor suppressor genes or oncogenes. For example, it is known that acetylation controls Notch function.[110] This example provides additional clues into how these drugs might affect the balance between growth and survival pathways of tumor cells. Other studies have highlighted that the relative proportion of different HDACs in tumor cells might lead to dysregulated growth. For example, PTCL tissue is known to be characterized by overexpression of HDAC1, HDAC2, and HDAC6 as well as acetylated histone 4 (H4).[111,112] Although it is not known precisely what genes are affected by the dysregulation of these HDACs, it clearly provides additional insight into the mechanism by which this class of drugs might be able to affect a unique set of intracellular pathways in PTCL.

The first HDAC inhibitor approved for the treatment of cancer was vorinostat, or SAHA.[113] Vorinostat is a hydroxamic acid derivative known to be a potent class 1-2 inhibitor of HDAC. Early developmental clinical studies performed with both intravenous and oral vorinostat demonstrated that the drug could inhibit HDACs, leading to accumulation of acetylated H3/H4.[114,115] These studies also demonstrated that the drug was well tolerated for extended periods of time, with dose-limiting toxicities of fatigue, diarrhea, and anorexia for the oral formulations, and myelosuppression for the intravenous formulations. Expanded phase II experiences with vorinostat confirmed single-agent activity in Hodgkin disease–transformed lymphomas and CTCL. These data gave rise to pivotal studies in CTCL leading to FDA approval in 2006.

Another HDAC inhibitor has been shown to be more active in PTCL, depsipeptide, also known as *romidepsin*. Romidepsin is a potent macrolide HDAC inhibitor isolated from *Chromobacterium violaceum*. An early phase I-II trial demonstrated that romidepsin exhibited marked single-agent activity in patients with relapsed or refractory CTCL and PTCL.[116] In fact, among 47 patients with relapsed or refractory PTCL, excluding patients with transformed mycosis fungoides (MF) and HTLV-1 ATL, which were included in the PROPEL study, an ORR of 38% was noted, including 8 patients who attained a CR. The most common toxicities were very similar to those reported for vorinostat and included nausea, fatigue, and transient thrombocytopenia. The median duration of response was roughly 8.9 months, and responses were seen in most of the PTCL subtypes studied. These data gave rise to an international, open-label, pivotal phase II study of romidepsin in patients with relapsed or refractory PTCL who had received at least one line of prior therapy. Of the 131 patients enrolled, 130 had histologically confirmed PTCL. The median number of prior therapies was two, with a range of one to eight. The ORR was 25%, which included 19 (15%) CRs, and the median duration of response was 17 months.[117] These data led to a conditional approval of romidepsin in patients with relapsed or refractory PTCL by the FDA in June of 2011.

More recent data have now suggested that pralatrexate and romidepsin appear to display synergistic activity in models of T-cell lymphoma.[109] These data are now being used as a rationale to support a multicenter phase I study that will define the maximum tolerated dose of this regimen, and then the tolerability and activity in a subpopulation of patients with PTCL.

Brentuximab Vedotin

Monoclonal antibodies have emerged as potentially important new therapeutic tools in the treatment of many subtypes of NHL. Monoclonal antibodies are now being developed against a host of other cell surface proteins, including the chemokine receptor CCR4, and other surface proteins like CD4 and more recently CD30. CD30 (also known as TNFRSF8) is a 120-kD transmembrane protein of the tumor necrosis factor family and a known tumor marker found on many kinds of lymphoma.[118,119] The receptor is found on the surface of only activated T cells, and some B cells. CD30 is found on virtually all cases of ALCL, and the majority of cases of HL, where it is seen on the surface of the Reed-Sternberg cell. It is also expressed by several nonlymphoid malignancies, including embryonal carcinoma and some cases of non–small cell lung cancer. Clinical trials with the chimeric anti-CD30 monoclonal antibody were uniformly disappointing in patients with ALCL and HL.[120,121] For example, among 38 patients with HL and 41 patients with ALCL treated with SGN-30, no responses were seen in patients with HL, whereas 2 patients with ALCL achieved a CR.[120] Similar results have been reported with other anti-CD30 monoclonal antibodies.

Conjugation of small molecules to highly targeted monoclonal antibodies to create an antibody drug conjugate offers a promising way to deliver highly toxic drugs to select populations of cells. The conjugation of a highly potent antimicrotubule agent, monomethyl auristatin E to the anti-CD30 monoclonal antibody creates a novel antibody drug conjugate called SGN-35, or brentuximab vedotin. Clinical trials of this drug in patients with HL and ALCL have demonstrated remarkable activity in these CD30-expressing diseases. A pivotal trial of brentuximab vedotin in patients with relapsed or refractory ALCL produced an ORR of 86%, with a CR rate of 57%.[71] These remissions were found to be very durable, with a median response duration of 12.6 months and a median duration of response among patients in CR of 13.2 months. The majority of patients enrolled in the study exhibited poor prognostic features: 72% of patients had ALK-negative ALCL, 63% of patients were refractory to front-line therapy, and 22% of patients had never responded to any prior therapy. These results recently led the FDA to grant accelerated approval to brentuximab vedotin in patients with ALCL. Ongoing studies are now exploring the benefits of this drug in combination with standard up-front chemotherapy regimens like CHOP.

KW-0761

Another novel cell surface protein for which there is now a targeted drug is the CCR4 chemokine receptor, which is encoded by the CCR4 gene. CCR4 has also recently been designated CD194.[122,123] The CCR4 protein belongs to the G protein–coupled receptor family and is a receptor for many different cytokines that influence the behavior of leukocytes. CCR4 is known to be expressed on T-helper type 2 (Th2) cells and regulatory T cells (Tregs). Several studies have demonstrated that CCR4 is expressed at relatively high levels on select T-cell neoplasms, including HTLV-1 ATLL. KW-0761 is a defucosylated humanized IgG1 anti-CCR4 monoclonal antibody

that enhances antibody-dependent cellular cytotoxicity and has been evaluated in multicenter phase I and II studies in patients with relapsed, aggressive CCR4-positive ATL.[124,125]

Patients received intravenous infusions of KW-0761 once a week for 8 weeks at a dose of 1.0 mg/kg. The phase II study of KW-0761 was conducted in 28 patients with relapsed or refractory ATL. The overall response rate was 50%, including eight complete responses, and the median PFS and OS were 5.2 and 13.7 months, respectively.[124] The most common adverse events were infusion reactions (89%) and skin rashes (63%), which were manageable and reversible in all cases. Albeit relatively early, this study demonstrated clinically meaningful antitumor activity in patients with relapsed aggressive ATL, with an acceptable toxicity profile. Further investigation of KW-0761 for treatment of ATL and other T-cell neoplasms are now warranted.

Miscellaneous Agents

The drugs mentioned above all represent agents that have been studied in a reasonable number of patients with T-cell lymphoma. In addition to these there are select other agents with very early and potentially promising signals of activity in PTCL. The proteasome inhibitors, including bortezomib and carfilzomib, have marked activity in multiple myeloma and mantle cell lymphoma.[126-128] Although the experience in PTCL is modest, 10 patients with CTCL and 2 with PTCL were treated with bortezomib at a dose of 1.3 mg/m^2 on a day 1, 4, 8, and 11 schedule. Although the ORR was reported to be 67%, dramatic responses were seen in patients with advanced CTCL, and one of the two patients with PTCL experienced a complete remission.[129] Emerging data have now demonstrated that the proteasome inhibitors potently synergize with the HDACI[130] and pralatrexate, which is leading now to combination studies in patients with PTCL.[108]

Another novel class of drugs with a signal of activity in the T-cell lymphomas includes the immunomodulatory drug lenalidomide. This class of drugs is thought to increase the immunologic synapse by increasing NK cell activity against the lymphoma cells. In one report, lenalidomide was administered orally for 21 days on a 28-day cycle at a dose of 25 mg daily in 24 patients with relapsed or refractory PTCL with an ORR of 30% being reported (7 responses among 23 evaluable patients), with no CR.[131] Responses were seen in patients with ALCL, AITL, and PTCL-NOS. The median PFS was 96 days. Similar results were reported among 10 patients with relapsed and refractory PTCL-NOS, where 3 CRs were reported.[132]

Preliminary reports from a phase II study of a novel Aurora-A kinase inhibitor, MLN8237/alisertib, in patients with aggressive NHL have recently demonstrated activity in patients with PTCL. Although the ORR was 32%, four of eight patients with relapsed or refractory PTCL experienced a response, including some complete remissions.[133] These data have now prompted a large international randomized study of alisertib in patients with relapsed or refractory PTCL, in which patients will be randomized to either the Aurora-A kinase inhibitor or a drug selected at the investigator's discretion (pralatrexate, romidepsin, or gemcitabine).

Future Directions

Over the past several years there has been a remarkable increase in our understanding of the diversity within the PTCLs. The appreciation that the mature T-cell lymphomas represent a vast spectrum of both indolent and aggressive subtypes, commonly associated with diverse clinical pictures with substantial global variation, has shaped how we now classify and think about these diseases. Even prognosticating the outcomes of patients with these diseases has become remarkably complicated, because each subtype of PTCL is now widely recognized as possessing its own unique clinical behavior and thus its own unique response to different therapeutic approaches. Eventually these prognostic models will be used to better risk stratify patients at diagnosis, allowing physicians to institute the optimal treatment plan earlier, which may include ASCT for select patients and allogeneic SCT for those with relapsed or refractory disease. Unquestionably, however, the increase in the number of new drugs available for the treatment of this group of diseases has begun to reshape our options when considering the management of patients with relapsed and refractory disease. As these new drugs are used with increasing frequency, each having significant single-agent activity in these traditionally chemotherapy-resistant diseases, the emergence of novel non–CHOP-based drug combinations will likely emerge, with the intent of tailoring the use of these combinations of drugs to patients with specific disease subtypes based upon an assessment of an individual patient's risk due to his or her specific disease subtype.

CUTANEOUS T-CELL LYMPHOMAS

The T-cell NHLs include a wide variety of clinical disorders with different prognoses. The WHO classification of hematopoietic malignancies suggests that more than 10 discrete clinicopathologic entities can be considered part of this family. This portion of the chapter focuses on the disorders that would be encompassed by the diagnosis *cutaneous T-cell lymphoma* (Table 84-6). The most common subtypes of CTCLs are the epidermotropic variants MF and the related leukemic variant, Sézary syndrome (SS).

Epidemiology

CTCLs account for 71% of the 3844 cutaneous lymphomas diagnosed in the United States between 2001 and 2010. MF and SS are the most common CTCL subtypes worldwide, constituting 54% of the CTCLs and an annual incidence of approximately four cases per million people.[135,136] MF and SS are the most common primary lymphomas involving the skin.[137,138] Data collected from the SEER program showed a rapidly increasing incidence from 0.2 cases per 100,000 people in 1973 to 0.4 cases per 100,000 people in 1984. This corresponds to approximately 1000 new cases each year in the United States. Whether this represented a true increase in incidence or was attributable to a better awareness and therefore more frequent recognition of this disease has not been resolved. Since that time the incidence rate of CTCL has stabilized at 0.36 cases per 100,000 persons, and the mortality rate has declined. The incidence of MF/SS increases with advancing age, as does the incidence of NHLs in general. The average age at presentation is approximately 50 years. Although cases in very young patients have been reported, most patients are at least 30 years of age.[139,141] MF/SS is seen in all racial groups. There is a 1.6:1 ratio of African Americans to whites and a 2.2:1 ratio of men to women with this disorder. MF is less common in the Asian population. Clusters of cases of MF/SS within families have been reported. An association with histocompatibility antigens AW31, AW32, B8, BW35, and DR5 has been described.[142] However, a solid genetic predisposition or inherited genetic defect has not been demonstrated.

Pathobiology

The T lymphocyte is central to the body's ability to mount an immune response and is the precursor of neoplastic cells in MF/SS. Sézary cells respond to phytohemagglutinin and perform T-cell immunoregulatory functions similar to normal lymphocytes.[143,144] The clonal nature of CTCL has been demonstrated by Southern blotting or polymerase chain reaction methods for analysis of the TCR.

The development of monoclonal antibodies directed against different T-cell antigens has allowed for more precise identification of surface markers on the malignant T cells.[145] Most cases of MF and SS are composed of the helper memory or effector T cells with a CD4$^+$CD45RO$^+$ phenotype. In most instances, the cells express the

pan–T cell antigens CD2 (the sheep erythrocyte receptor), CD3, and CD5. CD7 is a T-cell marker expressed in early differentiation, but usually absent in T cells homing to the skin. Although benign conditions may show some downregulation of CD7, marked deletion of CD7 is commonly used by the pathologist as an ancillary confirmatory test for CTCL. Flow cytometry provides a sensitive method for detecting early peripheral blood involvement in patients by detection of $CD4^+$, $CD26^-$ T-cell populations. A small subset of MF is characterized by the expression of CD8, a marker that is essentially never expressed in SS. Low expression of the α-chain component of the IL-2 receptor (CD25) is detected with heterogeneous expression by the malignant cells in less than half of the patients. The implication of this finding is of uncertain significance, because both activated T cells and immunoregulatory T cells can express CD25. Key signaling pathway alterations that affect MF and SS include Notch overexpression, Fas underexpression, and the association of PKC inhibition with apoptosis.[146-148]

Cytogenetic analyses have demonstrated numeric and structural chromosomal abnormalities in MF/SS,[149] although usually in advanced-stage disease. Hyperdiploidy and complex karyotypes are common. Nonrandom deletions of chromosomes 1, 6, 8, 10, and 17 have been reported with gains in chromosome 17q and 4p occurring in more than 25% of cases. Regions of the genome that include genes encoding the TCR do not appear to be involved, suggesting that the genetic basis for malignant transformation in MF/SS appears to be different from that involved in other T-cell malignant disorders.

Modest data exist on the aberrant expression of oncogenes and suppressor genes in MF/SS. Loss of heterozygosity is identified in 30% to 60% of patients, commonly at 9p, 10q, 1p, and 17p. Loss of heterozygosity in early stages of disease is associated with a threefold increase in mortality.[150] Various mutations involving the Fas pathway are commonly seen from the early stages of lymphomagenesis, reflecting an initial accumulation of abnormal lymphocytes secondary to abnormal proapoptotic pathways. Mutant forms of the P53 tumor suppressor gene are observed rarely, usually in tumor stage and large cell transformation of MF.[151] LYT-10, a member of the NF-κB family of transcription factors associated with translocations in lymphoid malignancies, is rearranged in a small proportion of cases.[152] However, BCL2, a gene whose rearrangement is characteristic of follicular B-cell lymphomas and which slows programmed cell death, is overexpressed in MF. Constitutive phosphorylation of STAT3 (a member of the transcription factor family that contributes to the diversity of cytokine responses) has been reported and suggests that these malignant T cells are activated.[145,153] Altered expression or release of select cytokines or their receptors, including IL-1, IL-2R, IL-4, IL-5, IL-6, IL-7, IL-8, IL-12, and TGF-β receptor II, has been noted.[154] IL-7 and IL-15 have been identified as growth factors for MF/SS and shown to regulate expression of the BCL2 and MYB oncogenes and stimulate DNA binding of STAT proteins.[155,156] There is recent evidence suggesting that SS and MF may follow different molecular pathways with dysregulation of genes encoding c-Myc and c-Myc regulatory proteins commonly associated with SS but not with MF.

The cause of MF/SS remains unknown. It is considered to be a sporadic disease without compelling evidence of transmissibility. Several viruses have been implicated in the pathogenesis of MF/SS, including HTLV-1 and HTLV-2, herpes simplex virus, human herpesvirus 6, and EBV. However, a viral cause of MF/SS has not been proven, and no epidemiologic evidence supports these hypotheses.

Investigators have suggested that prolonged antigenic stimulation via exposure to contact allergens or superantigen stimulation associated with infections may lead to enhanced immune responses with subsequent mutations in apoptotic pathway leading directly or indirectly to the development of MF/SS. Sézary cells respond in vitro to superantigenic exotoxins, and colonization by *Staphylococcus aureus* may influence disease activity.[157] Several reports suggested that exposure to metals or their salts, pesticides or herbicides, and organic solvents (halogenated or aromatic hydrocarbons) could be related to the development of MF/SS.[158] However, two well-designed case-control studies have failed to support these observations.[159,160]

Various theories have been advanced to explain the epidermotropism of malignant T cells in MF/SS. Organ-specific affinity to skin and other organs has been recognized in subsets of normal T cells. Homing of CTCL cells to the skin is probably mediated by more than one adhesion receptor mechanism. CTCL cells express cutaneous lymphocyte antigen, a skin homing receptor that interacts with E-selectin expressed by dermal venules.[145,161,162] Furthermore, the cutaneous lymphocyte antigen T lymphocytes also typically express the CCR4 chemokine receptor, which binds to chemokines produced by the skin, such as the CC-chemokine ligands 17 and 22. Peripheral blood mononuclear cells bind to cultured keratinocytes exposed to interferon-γ. The major histocompatibility complex class II proteins, along with intercellular adhesion molecule 1 present on keratinocytes, attract and bind lymphocytes. Additional chemokine

receptors, such as CXC chemokine receptors 3 and 4, as well as unique integrins, have been shown to have corresponding ligands or integrin receptors on dermal Langerhans cells, suggesting a relationship between the malignant T cells and host immune cells. The chemokine receptor CCR4 is expressed by a spectrum of CTCL cells, and an anti-CCR4 monoclonal antibody has significant activity against these diseases.[163]

An additional feature of MF/SS cells is the production of a cytokine profile consistent with Th2 cells.[164] The Th2 cells produce IL-4, IL-5, and IL-6, and they are inhibited by interferon-γ. The expression of immunomodulatory molecule IL-17 is also increased in MF and SS.[165] The Th2 cells are critical for stimulating antibody- and eosinophil-mediated responses. Hypergammaglobulinemia and eosinophilia are often seen in advanced cases of MF/SS and are consistent with a Th2 profile. Stimulation of Th2 cells inhibits the Th1 subpopulation of lymphocytes involved in cell-mediated immunity. Progression of MF/SS is associated with immune suppression as a result of depletion of this T-cell subset. The Th2 cytokine profile may explain the decrease in tumor-infiltrating lymphocytes during tumor progression. In addition to the effect of cytokines secreted by the neoplastic cells, the malignant $CD4^+$ cells express antigens (e.g., Fas ligand) that may directly mediate elimination of the $CD8^+$-infiltrating lymphocytes by induction of apoptosis.[166] $CD4^+$ T cells from MF skin lesions have an effector memory phenotype, whereas T cells from SS skin lesions display central memory characteristics[167] with the expression of the lymph node chemoattractant CCR7, which is not expressed in MF.

Clinical Presentation

Alibert[168] reported the first case of MF in 1806. His patient developed a skin eruption that progressed into mushroom-like tumors, prompting the term *mycosis fungoides.* Later in the 19th century, Bazin[169] defined the three classic cutaneous phases (patch, plaque, and tumor stage) of the disease. The recognition of the clinical triad of intensely pruritic erythroderma, lymphadenopathy, and abnormal hyperconvoluted cells in the peripheral blood led to the description of SS.[170]

MF is the prototype of CTCL observed in over 50% of CTCL cases. The initial course of patients with MF is usually indolent. Most patients give a history of antecedent skin lesions, usually nonspecific erythematous patches that can mimic eczema or psoriasis. In many cases, there is an orderly progression from limited patches to more generalized patches, plaques, tumors, and nodal or visceral involvement. However, some patients may present with extensive skin involvement and tumor lesions, whereas other patients have limited patch disease that remains unaltered for the patient's entire life. The characteristic patch lesion is typically poorly demarcated, lightly erythematous, and scaly, with a predilection for sun-protected areas, such as the lower abdomen or buttocks (Fig. 84-13). The texture can vary from poikilodermatous atrophic cases to serpiginous annular lesions or markedly keratotic patches. Plaque lesions are more indurated, have well-demarcated margins, and some scaling (Fig. 84-14). Plaques can arise from patch lesions or previously uninvolved areas of skin. The distinction between a patch and a plaque is often subjective, with a low rate of interpersonal agreement among experts. Tumor lesions tend to appear in advanced cases, frequently associated with previous patches or plaques, and are commonly associated with histologic evidence and large cell transformation. They can be located on any part of the body. Ulceration of these lesions is common, and secondary infection is a major cause of morbidity (Fig. 84-15). Tumors may be the initial presentation in a small percentage of patients (d'emblée presentation, Vidal and Brocq, 1889).

SS patients present with generalized desquamative erythroderma, pruritus, and circulating malignant cells. Peripheral blood usually shows a significant number or percentage of hyperconvoluted atypical lymphocytes (Fig. 84-16). Approximately 5% to 10% of all newly reported cases of CTCL are SS. In its most advanced form, patients with SS suffer from alopecia, ectropion, leonine facies, hyperkeratosis, nail dystrophy, fissuring of the palms and soles, and severe

Figure 84-13 ERYTHEMATOUS AND SCALY PATCH LESION OF MYCOSIS FUNGOIDES.

Figure 84-14 PLAQUE LESION OF CUTANEOUS T-CELL LYMPHOMA.

pruritus and cutaneous pain. Many other entities can clinically mimic this disease, including drug eruptions, atopic dermatitis, contact dermatitis, and erythrodermic psoriasis. A number of variant presentations of CTCL are described in the following sections.

Clonal Dermatitis

Clonal dermatitis is a term introduced by Wood et al[180] that included a variety of lymphocyte-rich dermatoses, often characterized by clonal T-lymphocyte proliferations. Clinically they exhibit a myriad of cutaneous presentations from poikiloderma (atrophic patches) to hyperpigmented areas resembling pigmented purpuric dermatosis.

Large Plaque Parapsoriasis

Large plaque parapsoriasis is the classic premalignant lesion of MF. It most commonly consists of a few scattered, erythematous to brown plaques that are usually larger than 6 cm.[172] There is a predilection for the buttocks and intertriginous areas. Histologic examination shows a superficial lymphocytic infiltrate with minimal nuclear atypia. Epidermotropism is scant or absent, and dermal fibrosis correlates with the chronicity of the process. Plaques can persist for decades before a frank evolution to MF occurs. Approximately 10% to 30% of patients ultimately develop an overt malignant transformation. Large plaque parapsoriasis is more likely to evolve into MF than small plaque lesions.

Figure 84-15 ULCERATED TUMORS ARISING FROM MYCOSIS FUNGOIDES PLAQUES.

Follicular Mucinosis

Follicular mucinosis manifests with grouped erythematous follicular papules or boggy or indurated nodular plaques, notably devoid of hair (Fig. 84-17).[173] There is a predilection for the head and neck area, especially the forehead, which has the highest density of pilosebaceous units. Histopathologic evaluation reveals cells in sebaceous glands often associated with destruction of hair follicle structures due to infiltration by a T-lymphocytic process. This condition may be idiopathic or associated with MF. Even idiopathic cases can be associated with clonal T-lymphocytic infiltration.[174] In general, patients older than 40 with a more generalized cutaneous involvement and a chronic course are more likely to develop associated MF. No cases of MF have been reported in children with alopecia mucinosa, although a few reports of Hodgkin disease have been reported in children with follicular mucinosis.[175] Patients with folliculotropic MF and follicular mucinosis are reported to have a worse prognosis, stage for stage, which may be caused by inability of topical treatment to penetrate to the deeper layers of the process.[176]

Lymphomatoid Papulosis

Lymphomatoid papulosis is characterized by recurrent crops of self-healing, red-brown, centrally necrotic, asymptomatic papules and nodules (Fig. 84-18).[177] This entity represents 10% to 15% of all CTCL cases. Patients may have a few lesions or more than 100 at a time. Histologic evaluation reveals an atypical $CD4^+$ lymphocytic infiltrate with a variable mixed inflammatory infiltrate (Fig. 84-19). These may be primarily small cerebriform cells similar to those seen in MF (type B), but most often there are larger $CD30^+$ cells with prominent nucleoli resembling Reed-Sternberg cells (type A). A third variety of lymphomatoid papulosis (type C) with sheets of anaplastic large cells resembling $CD30^+$ large cell lymphoma ($CD30^+$ LCL) has also been reported.[178] TCR gene rearrangement studies demonstrate a clonal origin. Although the typical course is usually indolent, spanning decades, approximately 15% of patients develop MF, HL, or NHL during their lifetime.[179] A direct link between lymphomatoid papulosis, CTCL, and Hodgkin disease was demonstrated in a patient with the three lymphoproliferative disorders arising from a common T-cell clone as shown by TCR gene studies.[180]

Pagetoid Reticulosis

Pagetoid reticulosis (i.e., Woringer-Kolopp disease) is a rare condition affecting young adults. It typically manifests with a solitary, hyperkeratotic, often verrucous plaque on the lower limb.[181] Biopsy results show atypical cerebriform lymphocytes with a perinuclear halo almost exclusively localized within the intraepidermal compartment.[182] Extracutaneous dissemination is exceedingly rare. Most cases have a $CD8^+$ phenotype, although $CD4^+$ cases or double-negative ($CD4^+$/CD8) cases have been reported. Frequently the tumor cells express CD30, but TCR gene rearrangement study results are often

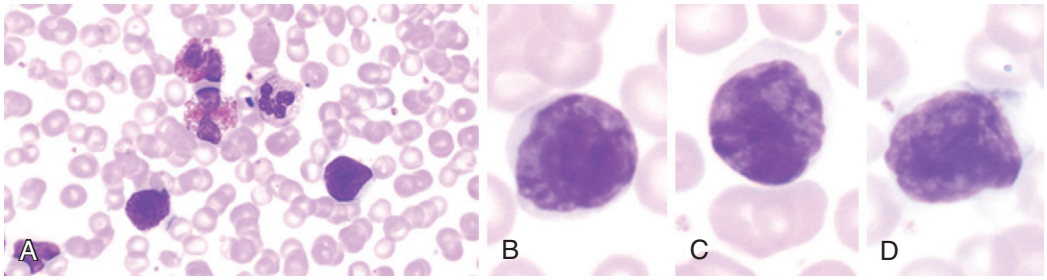

Figure 84-16 SÉZARY CELLS. Peripheral smear **(A)** with Sézary cells associated with eosinophilia. Note the cerebriform nuclei with fine chromatin **(B** to **D).** The hyperconvoluted nature of the nuclei is evident as complex nuclear folds seen through the chromatin.

negative. Whether pagetoid reticulosis should be considered a localized form of MF or a reactive pseudomalignant process is debatable. Although most cases have an indolent protracted course, generalized and sometimes aggressive variants have been reported.[183] Cases presenting with a solitary lesion are extremely indolent and could be considered a reactive or pseudolymphomatous process. At the opposite end of the spectrum there are patients with extensive ulcerative plaques formerly known as *generalized pagetoid reticulosis* or *Ketron-Goodman disease* that now are diagnosed as the $CD8^+$ aggressive intraepidermal T-cell lymphoma.

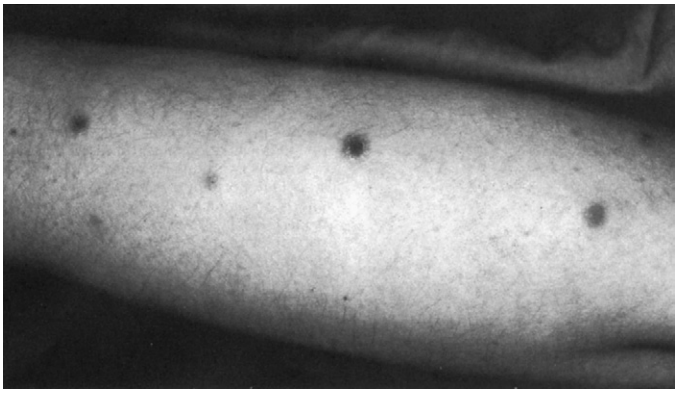

Figure 84-18 LESIONS OF LYMPHOMATOID PAPULOSIS APPEAR IN CROPS AND CONSIST OF ULCERATED PAPULES AND SCARS.

Granulomatous Slack Skin

In granulomatous slack skin syndrome, an extremely rare disorder, clonal $CD4^+$ T cells elicit a reactive granulomatous response that destroys the elastic fibers, rendering skin slack, fibrotic, and inelastic (Fig. 84-20).[184] Changes characteristic of MF are often found within the epidermis and papillary dermis, and the reticular dermis contains numerous histiocytes with multinucleated giant cells and elastophagocytosis. Some patients with granulomatous MF do not have destruction of the elastic fibers with slack skin changes. The differential diagnosis includes sarcoidosis and tuberculoid leprosy. An increased incidence of HL has been reported in this patient population.

Laboratory Manifestations

The gold standard in the diagnosis of MF/SS is light microscopic examination of a skin biopsy specimen. Characteristic findings include a band-like infiltrate involving the papillary dermis containing small, medium-sized, and occasionally large mononuclear cells with hyperchromatic, hyperconvoluted (cerebriform) nuclei and variable numbers of admixed inflammatory cells often expanding into adnexal structures (hair follicles and sweat glands).[154,185] Epidermal exocytosis of single or small clusters of neoplastic cells is a characteristic finding (Fig. 84-21, *A, C, D*). The presence of Pautrier microabscesses, defined as four or more atypical lymphocytes arranged in an aggregate in the epidermis, is classic but is seen in only a minority of cases. Reticular fibroplasia of the papillary dermis is also a common finding. Tumor-stage lesions demonstrate a more diffuse, superficial and deep, dermal infiltrate with fewer reactive cells and an absence of epidermotropism (Fig. 84-21, *B, E, F*). The malignant T-cell clone often evolves into large cell morphology during tumor progression, although rare cases show large cell morphology from the early patch lesions.[186] The presence of large cells in a skin lesion should be distinguished from "large cell transformation," which displays rapid skin, node, and visceral progression, is refractory to treatment, and is associated with poor survival. The histologic features in SS may be similar to those of MF. However, the cellular infiltrates in SS are more often monotonous, and epidermotropism may be absent.

Lymph node involvement initially involves the paracortical regions. Progression is associated with small to large clusters of atypical cells with preserved nodal architecture, followed by partial or total effacement of the node by neoplastic cells. Visceral involvement is a late clinical feature. Variable peripheral blood involvement can be demonstrated in all stages of skin disease, although it is most prevalent in patients with tumor or erythrodermic presentations. Patients with SS present with high circulating neoplastic cells, typically more

Figure 84-19 LYMPHOMATOID PAPULOSIS. Vesna Petrovic-Rosic and Mark Racz, University of Chicago.)*

than 1000 cells/mL (B2), but a lower count may be noted initially (B1). Bone marrow biopsy results are typically negative. However, some involvement may be detected by flow cytometry in many cases of SS or advanced MF but rarely influences management outside an investigational setting. A staging bone marrow aspirate and biopsy is not recommended, unless unexplained cytopenias are seen.

The malignant cells are typically $CD3^+$, $CD4^+$, $CD45RO^+$, $CD8^+$, and $CD30^+$ by immunohistochemical analysis. CD7 is not expressed by cells from the early disease stages. More aggressive variants and advanced forms of CTCL may have cells with multiple pan–T cell antigen deletions, especially CD2, CD5, and even CD4. TCR genes are clonally rearranged and can be documented in most cases by Southern blotting or polymerase chain reaction assays when a sufficient malignant infiltrate exists.

Analysis of peripheral blood may reveal an elevated LDH level, mostly in patients with high-blood-burden SS and bulky advanced MF. Eosinophilia and hypergammaglobulinemia are not uncommon is SS patients. A limited number of patients have an associated monoclonal gammopathy. Elevated serum β_2-microglobulin and IL-2 receptor levels have also been observed in advanced cases.

Imaging studies for classic MF/SS are generally of modest utility. Computed tomographic scans of the chest, abdomen, or pelvis should be reserved for patients with SS, nodal involvement, or CTCL variants. In an investigational setting, electron microscopy, cytogenetics, and molecular analyses have shown that a higher percentage of patients have occult involvement of internal organs.

Figure 84-20 LESIONS OF GRANULOMATOUS SLACK SKIN WITH DESTRUCTION OF THE DERMAL ELASTICITY.

Differential Diagnosis

Primary CTCL represents a heterogeneous group of disorders with considerable variability in histologic characteristics, phenotype, and prognosis. The Kiel Classification, the Working Formulation, and the Revised European-American Lymphoma (REAL) classification system were developed for NHLs and were not designed to provide an adequate characterization of the spectrum of CTCL. To address the deficiencies of the previously proposed systems, a more clinically useful classification was developed by the European Organization for Research and Treatment of Cancer (EORTC).[3] WHO has proposed a classification with nearly 90% concordance with the EORTC classification (see Table 84-6). A number of other disorders in which malignant T cells infiltrate the skin should be distinguished from MF/SS. These disorders are discussed in the following sections.

CD30 Lymphoproliferative Disorders

CD30 lymphoproliferative disorders include lymphomatoid papulosis, primary cutaneous ALCL, and a spectrum of borderline cases. By definition ALCL presents with single or multiple tumors measuring more than 2 cm and with a tendency for ulceration and steady growth. Borderline lesions are smaller but also tend to have a prolonged course, often with spontaneous resolution.

Lymphomatoid Papulosis

Lymphomatoid papulosis is characterized by recurrent crops of self-healing, red-brown, centrally necrotic, asymptomatic papules and

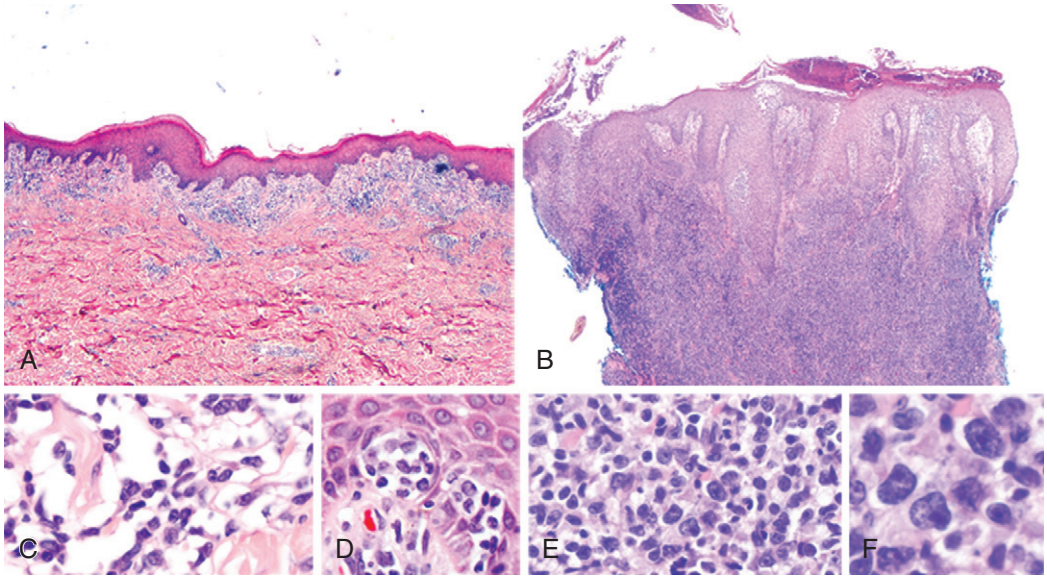

Figure 84-21 MYCOSIS FUNGOIDES, PLAQUE STAGE AND TRANSFORMED TUMOR STAGE. Plaque stage (**A, C,** and **D**) demonstrates a band-like infiltrate (**A** and **C**) with some epidermotropism in the form of Pautrier microabscesses **(D).** In the tumor stage (**B, E,** and **F**) there is a deep and dense infiltrate without significant epidermotropism. The cells are mostly large and atypical (**E** and **F**) and $CD30^+$ (not shown). *(Courtesy Drs. Vesna Petrovic-Rosic and Mark Racz, University of Chicago.)*

nodules. This entity represents 10% to 15% of all CTCL cases. Patients may have a few lesions or more than 100 at a time. Histologic evaluation reveals an atypical $CD4^+$ lymphocytic infiltrate with a variable mixed inflammatory infiltrate. These may be primarily small cerebriform cells similar to those seen in MF (type B), but most often there are larger $CD30^+$ cells with prominent nucleoli resembling Reed-Sternberg cells (type A). A third variety of lymphomatoid papulosis (type C), also considered borderline ALCL, presents with sheets of large cells resembling $CD30^+$ large cells. TCR gene rearrangement studies demonstrate a clonal origin. Although the typical course is usually indolent, spanning decades, approximately 15% of patients develop MF, cutaneous ALCL, and very rarely HL or NHL during their lifetime. A direct link between lymphomatoid papulosis, CTCL, and Hodgkin disease was demonstrated in a patient with the three lymphoproliferative disorders arising from a common T-cell clone as shown by TCR gene studies.

CD30-Positive Cutaneous T-Cell Lymphoma

Primary cutaneous $CD30^+$ LCL typically occurs in adults presenting with solitary or localized (ulcerating) nodules or tumors (Fig. 84-22).[187] Regional lymph node involvement is seen in 25% of patients at presentation. These primary cutaneous $CD30^+$ LCLs are probably closely related to lymphomatoid papulosis, regressing atypical histiocytosis, and primary cutaneous Hodgkin disease. The tumor has a favorable prognosis, and often complete or partial spontaneous regression occurs. This is in contrast to primary noncutaneous $CD30^+$ LCL, which can be seen in children or adults and which carries a poor prognosis.[188] These primary cutaneous lesions, in contrast to nodal or pediatric cases, have been shown to rarely have the chromosomal translocation t(2;5) associated with overexpression of the anaplastic lymphoma kinase (ALK negative). Histopathology consists of diffuse nonepidermotropic infiltrates with cohesive sheets of large $CD30^+$ tumor cells (Fig. 84-23). In most instances, the tumor cells have anaplastic morphologic characteristics, showing round, oval, or irregularly shaped nuclei; prominent (eosinophilic) nucleoli; and abundant cytoplasm. Less commonly, the neoplastic cells have a pleomorphic or immunoblastic appearance. Reactive lymphocytes are often present, but infiltrating eosinophils are often less conspicuous. The immunophenotype of this disorder is characteristically $CD4^+$, with more than 75% of neoplastic cells expressing CD30. In contrast to the poor outcome of MF that has transformed to a $CD30^+$ large cell variant, primary cutaneous $CD30^+$ LCLs are associated with an excellent prognosis. Radiotherapy is the preferred treatment for solitary or localized disease, with combination chemotherapy reserved for patients with generalized skin lesions or extracutaneous dissemination. Surgical excision may be adequate in many cases. In advanced cases, 5-year survival exceeds 30%.

Figure 84-22 LESIONS OF $CD30^+$ LARGE CELL LYMPHOMA WITH ULCERATION.

CD30-Negative Cutaneous T-Cell Lymphoma

These rare presentations often classified as CTCL, NOS, or d'emblée presentation, tend to have an aggressive clinical course. Patients present with localized or generalized plaques, nodules, or tumors.[189] Histopathologic evaluation demonstrates that infiltrates are nonepidermotropic with variable numbers of medium-sized to large pleomorphic T cells with or without cerebriform nuclei and immunoblasts. The tumor cells are $CD4^+$ with $CD30^-$ or expression restricted to a few scattered tumor cells. The infiltrate is often accompanied by a mixed infiltrate with reactive B cells and granulomatous or histiocytic component. Multiagent chemotherapy is used in most instances, with radiation therapy reserved for patients with localized disease. The 5-year survival rate is less than 20%.

Pleomorphic Small or Medium-Sized Cutaneous T-Cell Lymphoma

Pleomorphic small or medium-sized cutaneous T-cell lymphoma is a rare entity. Patients typically present with a single red-purplish nodule or tumor involving the head and neck regions. Rarely are multiple nodules noted. The neoplastic cells are accompanied by many reactive B cells and histiocytes, which has led to the hypothesis that they may arise from follicular T-helper cell population expressing BCL6, programmed death-1 (PD-1), and CD10. Typically, CD30 is negative, and CD4 expression is strong. TCR should be positive. In our opinion, cases presented with a single lesion should not be diagnosed as lymphomas because, despite its clonal nature, the prognosis is invariably benign. Recent publications have confirmed that these lesions were called *pseudolymphomas* in the past without significant

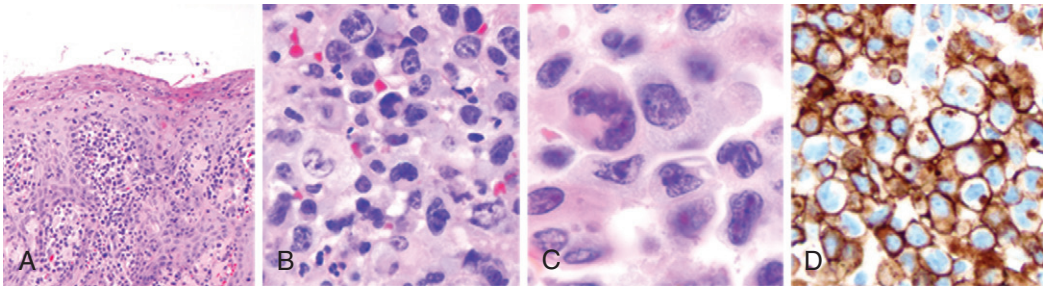

Figure 84-23 CUTANEOUS ANAPLASTIC LARGE CELL LYMPHOMA. Sheets of tumor cells are present in the dermis **(A)** and are associated with marked pseudoepitheliomatous hyperplasia. The cells are quite varied and bizarre **(B)** and frequently show abnormal "embryoid" shapes **(C)** constituting the "hallmark" cells. There is bright staining with CD30 **(D).** ALK staining (not shown) is typically negative.

consequences. However, patients presenting with multiple lesions are part of the d'emblée presentation and should be approached with caution, including full staging and systemic therapy. Patients with more generalized disease have been treated with regimens used for indolent NHLs. Five-year survival rates are 100% in unilesional cases and exceed 60% in patients with more extensive disease.

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma is a rare entity. Patients, typically younger and female, present with asymptomatic deep subcutaneous nonulcerated nodules and plaques involving the legs.[191,192] Systemic symptoms are common, including fevers, fatigue, and anorexia. Overlapping or preceding signs of lupus erythematosus or other autoimmune conditions are commonly observed. Histopathologic examination reveals a subcutaneous infiltrate with pleomorphic medium-sized T cells mixed with a reactive lymphoid infiltrate and some histiocytes. Tumor cell necrosis, karyorrhexis, and erythrophagocytosis are common findings. Differential diagnosis includes the frequently fatal but nonneoplastic cytophagic histiocytic panniculitis. Neoplastic infiltration of deep blood vessels can be noted in some cases.[193] Immunophenotyping reveals postthymic T-cell markers with $CD8^+$ phenotype and expression of cytotoxic markers like TIA-1 and granzyme B. By definition the tumor cells are negative for EBV markers and lack expression of the γδ heterodimer. However, T-cell clonality including the γ- or β-gene is commonly identified. The prognosis is fairly good with a 5-year survival rate over 80% with the exception of patients with a concurrent hemophagocytic syndrome (fevers, cytopenias). Cases in which the panniculitic findings coexist with lupus erythematosus may behave in a clinically indolent fashion.

Primary Cutaneous γδ-T-Cell Lymphoma

Cutaneous γδ-T-cell lymphoma is a rare condition that tends to present with extensive panniculitis-like plaques on the extremities with a tendency to ulcerate during the course of the disease.[192,193] A subset of patients present with single lesions resembling an infection process or with extensive chronic erythematous and scaly patches resembling MF. Several of our patients had comorbidities associated with immune suppression, including autoimmune conditions or other lymphoproliferative conditions or malignancies. Chronic antigen stimulation has been hypothesized to play a role in the pathogenesis of cutaneous γδ-T-cell lymphoma. Patients often present with a high level of LDH and constitutional symptoms and succumb to the disease, often associated with hemophagocytic syndrome. For the most part, all therapies have shown modest effectiveness. Sustained remissions have not resulted from radiation, immune therapy, or multiagent chemotherapy. However, a case with complete remission for 23 months following ASCT has been observed. Cytotoxic features like necrosis, hemorrhage, and vasculitis are commonly encountered. The immunophenotype is characterized by CD4/CD8 double negativity (with some $CD8^+$ cases), lack of CD5 expression, and expression of cytotoxic granules.

Primary Cutaneous Aggressive Epidermotropic $CD8^+$ T-Cell Lymphoma

This extremely rare condition, formerly known as generalized pagetoid reticulosis or Ketron-Goodman syndrome, constitutes less than 1% of all cutaneous lymphomas.[194] The term *Berti lymphoma* is often used to refer to this condition. Men are affected more commonly, and patients present with extensive erosive patches with frequent mucosal involvement. Occasionally the lesions are exophytic and hemorrhagic, resembling pyogenic granuloma. The course is invariable and rapidly fatal with exceptional cases reported surviving following ASCT. Histologically the infiltrate is markedly epidermotropic and adnexotropic, infiltrating into hair follicles and sweat glands, eventually becoming hemorrhagic and ulcerated. The cells are also of intermediate size, always expressing CD8 as well as other T-cell markers such as CD7 and CD45RO.

Extranasal Natural Killer/T-Cell Lymphoma

EBV-induced extranasal NKTCLs rarely appear in the skin as the initial site of presentation.[195] This condition is mostly reported in Asia and Latin America with rare cases seen in the United States. Although occasional cases remain localized in the skin, most of these lymphomas eventually involve other sites commonly affected in cytotoxic lymphomas such as the testes or the gastrointestinal tract. A careful ear, nose, and throat evaluation to rule out nasopharyngeal involvement is important. The lesions are mostly large ulcerated tumor lesions with hemorrhagic and necrotic appearance. Histologically the tumor is composed of a deep infiltrate with intermediate-sized lymphocytes with cytotoxic changes, hemorrhage, and necrotic debris. A histologic landmark is the presence of angiocentric and angiodestructive features. The immunophenotype is characterized by the expression of CD3ε in the cytoplasmic membrane, as well as CD56. Cytotoxic cytoplasmic granules are always identified, and EBV in the tumor cells can be demonstrated by the expression of EBER or LMP1. A lymphoproliferative disorder resembling hydroa vacciniforme has been reported almost exclusively in Latin America, especially in the Andes region, where the combination of high altitude with intense ultraviolet rays triggers this process, which is mostly seen in vulnerable indigenous patients. The patients present with facial edema, hepatosplenomegaly, and necrotizing hemorrhagic lesions triggered by sun exposure or arthropod bite reactions. These conditions are all very aggressive, and patients often succumb to hemophagocytic syndrome. Multiagent chemotherapy has not been effective, and perhaps the only hope for these individuals is an allogeneic SCT.

Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis is a rare multiorgan disease of the lungs, nasopharynx, joints, and peripheral and central nervous systems.[196] Cutaneous involvement occurs in 25% to 50% of patients. Though nodules are most common, some patients have nonspecific macules, papules, or ulceration. Histologic evaluation reveals an angiocentric, polymorphous infiltrate of atypical lymphocytes and histiocytes surrounding and invading blood vessels within the dermis. Molecular and immunologic studies suggest a mature clonal helper T-cell process. However, reports have suggested a massive reactive T-cell infiltrate driven by a small number of clonal B cells.[195]

EBV DNA sequences are frequently present, and their role in the pathogenesis of this disorder remains poorly defined. Though the clinical course is variable, the prognosis for patients with diffuse pulmonary involvement or evolution to high-grade lymphoma is poor, with a median survival of less than 2 years. Treatment that depends on histologic findings and extent and location of disease may include corticosteroids, radiotherapy, and chemotherapy. Interferon has shown significant activity against this disease.[196] Related conditions include the recently reported EBV-induced mucocutaneous ulcer seen in immunosuppressed patients and B-cell lymphomas of older adults.

Adult T-Cell Leukemia

ATLL is in most instances a rapidly progressive T-cell neoplasm expressing a helper phenotype that is described earlier in this chapter.[197,198] It is endemic in southern Japan and the Caribbean islands and is associated with the retrovirus HTLV-1. However, most HTLV-I–infected patients remain asymptomatic, and only 2% to 4% develop ATL. The clinical presentation is polymorphous and can

resemble MF or SS. Cutaneous lesions are variable, ranging from a rash simulating a viral exanthem, to annular lesions resembling erythema multiforme, to large tumors and plaques similar to MF (Fig. 84-24). Advanced stages of the disease, which affects a younger population than seen with MF, are characterized by visceral involvement, immunodeficiency, elevated LDH level, and hypercalcemia. Malignant lymphocytes often have convoluted or multilobed nuclei and can be detected in the peripheral blood in 75% of patients. The neoplastic T cells express high levels of the IL-2 receptor (CD25). For purposes of treatment and prognosis, it is wise to view ATL as a spectrum with two subgroups, acute and all others, with treatment, though inadequate, reserved for those with acute ATL. Therapeutic options include multiagent chemotherapy and antibody or recombinant toxins directed against the IL-2 receptor. Patients with acute ATL have poor survival rates, with a median duration of 4 to 6 months. Patients with disease that is not "acute" are considered to have "smoldering" disease and have lesions that may wax and wane in size and shape despite treatment.

Prognosis

The goals of treatment in MF are the relief of symptoms with improved quality of life, generally through prevention or delay in development of advanced skin disease and improvement in cosmetics. Despite some uncontrolled clinical trial results that have been reported to suggest "cures" in this disease, the general perception remains that this disease is not curable with standard therapies available today. The disease behaves similarly to other low-grade lymphomas, with periods of remission gradually becoming shorter with subsequent therapeutic interventions. Unlike B-cell low-grade lymphomas, however, advanced-stage MF is associated with a relatively short median life expectancy. Patients with significant nodal involvement (LN3 or LN4) or extensive skin involvement (T4) have median life expectancies of 30 to 55 months[199,200] (Table 84-7)]. A driving force in the development of treatments for this disease is the goal of altering the natural history for this group of poor-prognosis patients.

Figure 84-24 SKIN LESIONS IN ADULT T-CELL LYMPHOMA/LEUKEMIA.

No clinical trial has determined that aggressive early therapy is better than sequential palliative approaches or investigational approaches,[201] and new treatments continue to be developed and tested for these patients.

In 1979 the staging committee at an international workshop on MF proposed a staging system based on the international tumor-node-metastasis (TNM) system (see Table 84-7).[202] This classification was based on the evaluation of 347 patients and a multivariate analysis of potential prognostic factors. This group identified several independent prognostic factors: extent of skin disease at diagnosis (T), type of lymph node (N) involvement, presence or absence of peripheral blood (PB) involvement, and presence or absence of visceral (M) involvement. The group also translated this staging into a recommended clinical staging system (see Table 84-7). Investigators at the National Cancer Institute retrospectively analyzed 152 patients who

Table 84-7 TNM Staging System for Cutaneous T-Cell Lymphomas

Classification	Description
T	Skin
T0	Clinically or histopathologically suspicious lesions
T1	Limited plaques, papules, or eczematous patches covering 10% of the skin surface
T2	Generalized plaques, papules, or erythematous patches covering 10% of the skin surface
T3	Tumors (one or more)
T4	Generalized erythroderma Pathology of T1 to 4 is diagnostic of a cutaneous T-cell lymphoma. When more than one T stage exists, both are recorded and highest is used for staging. Record other features if appropriate (e.g., ulcers, poikiloderma, scale)
N	Lymph nodes
N0	No clinically abnormal peripheral lymph nodes
N1	Clinically abnormal peripheral lymph nodes (record number of sites)
NP0	Biopsy performed, not CTCL
NP1	Biopsy performed, CTCL
PB	Peripheral blood
PB0	Atypical circulating cells not present (≤5%)
PB1	Atypical circulating cells not present (>5%), record total white blood cell count, total lymphocyte count, and percentage of abnormal cells
M	Visceral organs
M0	No visceral organ involvement
M1	Visceral involvement (must have pathologic confirmation), record organ involved
Staging	
Stage IA	T1, N0 NP0, M0
Stage IB	T2, N0 NP0, M0
Stage IIA	T1-2, N1 NP0, M0
Stage IIB	T3, N0 NP0, M0
Stage III	T4, N0 NP0, M0
Stage IVA	T1-4, N0,1 NP1, M0
Stage IVB	T1-4, N0,1 NP0,1, M1

CTCL, Cutaneous T-cell lymphoma; *TNM,* tumor-node-metastasis.

underwent uniform pathologic staging.[203] They were able to identify three distinct prognostic groups. Good-risk patients had plaque-only skin disease without lymph node, blood, or visceral involvement, and a median survival of more than 12 years. Less than 10% of patients with stage 1A (limited patch) and less than 30% with stage 1B (extensive patch or plaque) progress to more advanced disease. Intermediate-risk patients had skin tumors, erythroderma, or plaque disease with lymph node or blood involvement (but no visceral disease) and a median survival of 5 years. Poor-risk patients had visceral disease or complete effacement of lymph nodes by lymphoma, and a median survival of 2.5 years.

In addition to the classic TNM staging, implementation of techniques such as flow cytometry, cytogenetic analysis, and determination of nuclear contour indices may also improve diagnostic and prognostic specificity. Flow cytometry and cytogenetic analysis are complementary techniques. Flow cytometry allows the detection of cell populations with a normal (diploid) number of chromosomes versus abnormal (aneuploid) numbers, and cytogenetic analysis precisely identifies the individual chromosomal structure and number. Bunn et al[204] demonstrated that in MF/SS the presence of aneuploidy during the clinical course was associated with more aggressive disease. Hyperdiploid cell clones were demonstrated in patients with large-cell histology, aggressive disease, and shortened survival time. Specific chromosomal deletions also influenced prognosis.[205]

The nuclear contour index has been used by several groups in an effort to separate "benign" cutaneous lymphocytic disorders, such as lymphomatoid papulosis and pityriasis lichenoides, from MF/SS.[206,207] Electron microscopy allows the calculation of a value based on the degree of nuclear folding; this nuclear contour index is significantly greater in patients with MF than in other benign conditions.

The density of epidermal Langerhans cells in biopsy samples, as determined by immunoperoxidase stains, has been identified as a prognostic feature.[208] Epidermal Langerhans cells are necessary for antigen recognition and processing in the normal immune response. Patients with Langerhans cell densities greater than 90 cells/mm^2 had a significantly reduced risk for death from MF/SS as compared with those with lower densities. There was no prognostic significance identified for the presence or absence of CD30-positive cells. It has been noted that the presence of cytotoxic CD8$^+$ T lymphocytes in the skin infiltrate is associated with a more favorable prognosis.[209]

Occasionally patients may develop a more clinically aggressive lymphoma concurrent with a change in the histologic appearance of the neoplastic cells and the pace of their disease. This progression from typical small, convoluted lymphocytes to larger lymphocytes, such as those associated with large cell lymphoma, has been documented.[210,211] Whether this conversion is secondary to prior therapeutic modalities used remains uncertain.

The gold standard for the diagnosis of MF is still routine histopathologic evaluation with adequate clinical correlation. Early lesions of MF are frequently accompanied by heavy infiltrates of benign reactive T cells, hampering the detection of abnormal T-cell clones by any laboratory method. Hence most adjuvant laboratory methods are not helpful at the precise time when they are most needed.

Therapy

Therapy can be conveniently divided into two approaches: topical (skin directed), such as psoralen plus ultraviolet A (PUVA), topical chemotherapy application (nitrogen mustard or carmustine), external beam radiotherapy, and total-skin electron beam radiotherapy, and systemic (skin and viscera directed), such as interferons, oral or parenteral chemotherapy, photopheresis, oral retinoids, and investigational new compounds (Table 84-8). No studies have demonstrated that one topical therapy is more effective than another, and patient and investigator preference remains the most important discriminating factor governing choice. However, as the biology of the neoplastic cell has become better understood,[202] it is clear that some therapies may actually have topical and systemic effects through alterations in the body's cytokine milieu and ability to mount a host response against the neoplastic cell.[203] Furthermore, knowledge regarding signaling pathways in the neoplastic cells in MF/SS offers hope that future development of targeted treatment approaches will soon be available. Investigational approaches combining therapies also remains an active research strategy (see box on Algorithm for Care of Patients With Mycosis Fungoides or Sézary Syndrome).

Phototherapy

8-Methoxypsoralen (8-MOP) is a member of a family of photoactivated compounds (furocoumarin derivatives), which may inhibit DNA and ribonucleic acid (RNA) synthesis through formation of monofunctional or bifunctional thymine adducts, gene mutations, or sister chromatid exchanges.[212,213] The cross-strand formed between DNA strands results in a halt in cell division, as well as oxidative damage to cytoplasmic organelles and cell membranes. These drugs are active only if the tissue containing the psoralen compound is exposed to ultraviolet A (UVA). The mechanism of cell cytotoxicity for many cancer therapies involves the induction of apoptosis. Yoo et al[217] demonstrated that peripheral blood mononuclear cells from SS patients and controls exposed in vitro to PUVA undergo apoptosis. Unfortunately, normal and neoplastic lymphocytes were equally sensitive to the apoptosis induced by PUVA (as opposed to with psoralen alone). However, macrophages appeared to be resistant to apoptosis induction and phagocytized apoptotic lymphocytes (but not nonapoptotic lymphocytes). Apoptosis induction may be the ultimate end point yielding benefit, but an immunologic effect due to monocyte phagocytosis and antigen presentation resulting from effector cells may also be present.

Photochemotherapy units with UVA lamps emit a continuous spectrum of long UVA in the range of 320 to 400 nm with peak emission between 350 and 380 nm. Initial exposure times of patients to high-output UVA are based on the degree of pigmentation before therapy, history of ability to tan, and the output of the photochemotherapy units. Exposure times are increased with each treatment depending on the patient's response and evidence of erythema. The initial UVA dose is between 0.5 and 2.0 J/cm^2 and can be increased by approximately 0.5 J/cm^2 per treatment as tolerated. The psoralen compound is ingested 2 hours before the UVA exposure. Topical psoralen protocols are also available. UV-blocking glasses should be worn for 24 hours after administration of 8-MOP. Therapy is typically given three times weekly until complete clearing occurs. The frequency of treatments can then be reduced, but some maintenance therapy (once every 2 to 4 weeks) may prolong the duration of remission. As data have emerged regarding the long-term risks of second skin malignancies after PUVA, the advisability of this maintenance therapy has been questioned.

CHOP, Cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), and prednisone; *CVP,* cyclophosphamide, vincristine, and prednisone; *EPOCH,* etoposide, prednisone, vincristine (Oncovin), cyclophosphamide, and hydroxydaunomycin; *MF,* mycosis fungoides; *nSS,* Sézary syndrome.

Initial trials using PUVA benefited psoriasis patients.[215] Clinical trials with PUVA for patients with MF soon followed.[216] These studies all demonstrated high rates of remission in the early stage (patch or plaque stage of disease). The Scandinavian study group reported a 58% CR rate for these patients within 4 to 12 months of initiation of therapy.[217] Maintenance therapy was associated with a remission duration of up to 53 months. In these early studies, the same group also reported a surprisingly high rate of objective remissions in tumor-stage patients of 83%.[218] In a large series, 82 patients were followed for a median of 43 months.[219] An ORR was observed in 95% of patients, with a 65% complete clearance rate. Ninety percent of these patients had early-stage disease (stage IA-IIA). A single patient with tumor-stage disease attained a short remission with PUVA alone. Two of six patients with generalized erythroderma cleared completely (no evidence of circulating neoplastic lymphocytes). Given the difficulty in treating advanced-stage patients with PUVA alone, we usually restrict PUVA therapy to patients with stage IA-IIA disease (see Table 84-7), monitoring patients with tumor disease closely for progression.

Side effects associated with PUVA are quite tolerable. Nausea or vomiting due to psoralen ingestion is observed occasionally, and erythema, pruritus, and chronic dry skin are effects of the UVA

damage. Long-term PUVA exposure has been associated with a number of delayed effects. These include dry skin, lichenification, keratosis, and rarely amyloid deposition in the skin.[220] Most important is the late development of iatrogenic (basal and squamous) carcinomas,[221] secondary malignant melanomas of the skin,[222] and rarely cataract formation. Because the cumulative dose of PUVA is correlated with the risk for developing a second skin cancer, routine use of maintenance therapy may be less desirable, especially for patients with an excellent prognosis (stage IA). Despite these problems, the long remissions induced, the ease of administration, and the lack of interactions with other therapeutic modalities make PUVA an attractive early intervention.

Narrow-band UVB (wavelength of 311 nm) is emerging as a valid alternative to PUVA for patients with limited patch or plaque disease. Although probably not as effective as PUVA, initial studies reported response rates near 70%.[223] The advantages of narrow-band UVB are that oral psoralen is not required and there may be less of a photocarcinogenic effect. The role for maintenance therapy has not been established.

UVA-1 is a modality of phototherapy that uses high-energy UVA1 (340 to 400 nm) output, which penetrates deep into the dermis. Resolution of tumor lesions has even been reported using this therapeutic approach.[224] However, the reduction in circulating $CD4^+$ cells raises the possibility that chronic use of this modality could be immunosuppressive.

Radiation Therapy

The CTCLs have been shown to be radiosensitive.[225] External-beam radiation adequately controls local areas of otherwise resistant MF or provides palliation in cases of bulky tumor lesions.[226,227] Unfortunately, the cumulative dosage that can be given to patients over time is limited due to organ toxicity. Side effects consisting of leukopenia, thrombocytopenia, and radiation-induced dermatitis may prevent long-term therapy with other agents. Newer techniques involving total nodal irradiation, fractionated total body irradiation, and limited fraction lesional irradiation all may have a role to play in the development of multimodality approaches to this disease. There has been little comparative research into methodology for external beam radiation that provides guidance to clinicians.

We recently reviewed our outcomes with a single fraction of external beam radiation, which was hypothesized to optimize convenience and minimize expense to patients.[228] Two hundred seventy individual lesions in 58 patients were primarily treated with more than 700 cGy (97%). With a mean follow-up of 41 months, 94.4% of lesions completely responded, and 3.7% partially responded. Predictors of poor response included lower extremity lesion, tumors, and lesions exhibiting large cell transformation. Lesions treated with electrons had a higher complete remission rate than those treated with photons. Cost estimates suggested multifractionated radiation was 200% more expensive than the single fraction.

The limitations of external beam radiation led to increasing use of electron beam radiotherapy for cases of MF confined to the skin. Linear accelerator–generated electron beams are scattered by a penetrable plate placed at the collimator site. The energy of the electrons is reduced to 4 to 7 MeV and allows adequate field distribution. Because of this low energy level, the beam only penetrates the surface several millimeters to 1 cm into the dermis. Patients may be treated using six-field or rotational treatments.[229,230] The total skin surface can be treated without significant internal organ toxicity. Most patients are able to tolerate total doses of approximately 3000 to 3600 cGy over an 8- to 10-week period.[230]

An excellent review compared results of external beam therapy at Stanford University with those achieved in Hamilton, Ontario.[231] The results cited in this paper reflect the extensive expertise of both centers in the delivery of this therapy and may not be applicable to centers where this approach is less frequently used. For patients with stage IA-IIA disease (see Table 84-7), almost 65% to 95% of patients achieved a complete remission. Treatment delivered without adjuvant therapies is associated with a relatively high rate of relapse in patients of all stages except stage IA. Ten-year relapse-free survival rates at the two centers ranged from 33% to 52% for this good-prognosis group. However, for stage IB and more advanced disease, 10-year unmaintained remission rates were only 16% or less. Higher-risk patients may be "induced" with external beam radiation and then placed on topical chemotherapy or systemic treatments such as extracorporeal photopheresis for "maintenance." Still the benefits of therapy may extend beyond crude estimates of relapse rates or survival. Patients with tumor lesions, generalized erythroderma, peripheral blood or nodal involvement, and even visceral spread can be successfully palliated with electron beam radiation therapy as well. Side effects, however, can be occasionally extreme, including scaling, dryness of skin, erythema, edematous extremities, telangiectasia formation, skin ulceration, and hair or sweat gland loss (usually transient but occasionally permanent). Careful radiation dosimetric techniques are required to ensure adequate skin treatment without excessive organ toxicity.[230] We do not use electron beam radiotherapy early in the course of the disease because other topical therapies have been developed that yield similar response rates with less potential toxicity. The long duration of remissions observed in patients with stage IA disease does not equate with cure, because their life expectancy is essentially the same as age-matched controls, and these patients may simply have indolent biology. One group has reported our experience with multiple courses of therapy.[232] They re-treated 15 patients with relapsed MF a mean of 41 months after the initial course of electron beam therapy. All patients had received intervening therapies for disease control. Eleven of the 15 had a CR with their first cycle of radiation. The second course achieved six CRs and nine partial remissions. The median duration of the initial CR was 11 months. The median duration of CR to the second course of therapy was only 3 months, suggesting radioresistance had developed between the first and second cycles in many patients. In general, toxicity was thought to be tolerable.

Topical Drug Therapy

The initial therapies for MF focused on treatment of the skin disease. Patients have long been known to benefit from the application of topical steroids. Zackheim et al[236] reported a 63% complete response rate with twice-daily applications in stage T1 patients but only a 25% complete response rate in stage T2 patients. Novel approaches by dermatologists to apply chemotherapy topically to avoid systemic therapy complications have also been devised. Mechlorethamine hydrochloride was the first topical agent evaluated to demonstrate efficacy in MF.[234] The solution used for topical application contains 10 to 20 mg of mechlorethamine dissolved in 50 to 100 mL of tap water (no vesicant activity at this low concentration). Although several methods may be used for administration, self-administration at home to the entire skin surface is preferred. The concentration may need to be varied depending on patient tolerance and sensitivity.[235] The time to initial response is usually short, approximately 1 to 2 weeks, but long-term application is usually required to obtain the maximum response.

Several large studies have been completed demonstrating the benefit of mechlorethamine, especially in early-stage disease.[236,238] One by Vonderheid et al[237] reported their experience with topical mechlorethamine and found that it compared favorably with results achieved with electron beam treatment. CRs were seen in 80%, 68%, and 61% of patients with limited plaque, extensive plaque, and tumor lesions, respectively. The corresponding median duration of remissions was in excess of 15, 5, and 12 months, respectively. It is difficult to draw definite conclusions from these data, because many patients included in the analysis also received intravenous mechlorethamine or methotrexate, and some may have received radiation therapy. Several patients have relapsed as long as 8 years after the completion of therapy, suggesting that follow-up times must be long to compare various topical therapies for early-stage disease. Hoppe et al[97,232] confirmed these findings using an ointment-based

(Aquaphor or polyethylene glycol) topical mechlorethamine, which may be associated with a lower incidence of cutaneous sensitivity. Formal testing of polyethylene glycol formulations for the treatment of early-stage disease has been completed, and an assessment of relative benefit compared to standard formulations is awaited.

For early-stage disease, topical mechlorethamine offers an efficient, convenient (outpatient treatment), and relatively inexpensive treatment option. Side effects consist of delayed hypersensitivity in approximately 35% of patients, although ointment-based solutions appeared to offer a reduced risk for allergic contact dermatitis. Once hypersensitivity develops, patients can be desensitized by injecting minute daily doses of mechlorethamine over a period of several weeks.[238] This should be done only in a medical setting with appropriate anaphylaxis precautions observed. Other investigators had difficulty replicating the results using this risky procedure, and topical desensitization has become much more common. Constantine et al[242] propose that therapy should be transiently discontinued until clearance of the allergic dermatitis is achieved (using topical steroids if necessary). Then 0.01 to 0.1 mg per 100 mL of the drug should be applied daily for 1 week. If this dilution is tolerated, the dosage is doubled weekly until the dose achieved is often identical to the initial concentration that induced the hypersensitivity.

Some clinicians, however, believe that a mild hypersensitivity reaction may have beneficial antitumor effects. Ratner et al[243] previously demonstrated that plaque lesions of MF cleared when exposed to topical doses of 2,4-dinitrochlorobenzene, a known universal inducer of delayed hypersensitivity responses. Anergic individuals failed to improve. Other known sensitizing agents yielded similar but less dramatic responses. Some hypersensitivity may be beneficial; the generalized erythroderma and pruritus are usually poorly tolerated when severe, however, and some alteration in therapy is required.

An increased risk for secondary skin cancers in patients receiving long-term mechlorethamine has been observed. Some physicians have expressed concern regarding the safety of family members or health care workers secondarily exposed to the topical solutions. Home treatment with topical mechlorethamine has been shown to result in aerosolized drug levels, which may result in mucous membrane or ocular irritation.[241] However, we are unaware of any documented adverse outcomes and believe this to be a theoretical concern rather than a practical one.

Several other topical agents have been tested and shown to be of benefit in the treatment of MF, including cytarabine, dianhydrogalactitol, dacarbazine, guanazole, teniposide, hydroxyurea, thiotepa, and methotrexate.[242] However, topical carmustine is the only agent that has demonstrated clinical use.[243] A stock solution is created with 300 mg carmustine in 150 mL of 95% ethanol (sufficient for 30 days of treatment). The patient then adds 5 mL of the 0.2% stock solution to 60 mL of room-temperature tap water. This solution can then be applied to the general body surface, with the exception of the head, genitals, palms, soles, and intertriginous zones, unless involved by disease. Applications are planned to occur daily for 2 to 6 months, if necessary. Brief exposures to double-dose solution can be used for resistant disease. Results in 188 patients with patch or plaque disease demonstrate efficacy similar to that of topical mechlorethamine.[243] For limited patch disease, there was a failure-free rate of 90% at 3 years. For more extensive patch-stage disease the freedom from treatment failure rate at 3 years was 62%. Some patients have been managed for as long as 10 years with topical carmustine. Side effects of contact dermatitis are less frequent with this agent, but systemic side effects, mainly leukopenia, are more common. This drug may be helpful for the treatment of patients who do not tolerate topical mechlorethamine, because there is no cross-sensitivity.

Hamminga et al[247] performed one of the few prospective trials comparing total-skin electron beam radiation to topical mechlorethamine. A total of 42 patients with MF localized to the skin (no documented nodal or visceral involvement) were treated. Patients were not randomized to their treatment; rather, the physician based the decision on patient health, availability of the linear accelerator, and the distance the patient lived from the clinic. In patients with minimal skin disease, no difference in outcome was observed. In more advanced skin disease, a trend toward superior initial response was seen with electron beam therapy, but there was a high relapse rate in those patients, necessitating subsequent therapy.

Systemic Chemotherapy

Currently systemic chemotherapy is reserved for those patients with relapsed or refractory disease after topical interventions or for those patients with advanced nodal or visceral disease at presentation. Many of the patients treated with chemotherapy have also previously been treated with cytokine-based or other nontraditional chemotherapeutic agents before systemic chemotherapy is considered. With that in mind, a number of trials have been published reporting results using agents developed many years ago for other indications but still in use for the treatment of MF/SS today. Recently, novel agents are being increasingly studied for efficacy in MF/SS based upon a rationale developed with molecular or proteomic data. An example of such agents is the HDACI. Vorinostat (SAHA) has been approved by the FDA for the treatment of the cutaneous manifestations of CTCL in patients in whom bexarotene therapy (see Retinoids) has failed,[113,245-247] and a related HDAC inhibitor, romidepsin (depsipeptide or FR901228), was more recently approved for the treatment of CTCL and PTCL. The mechanism of action of these drugs has been described previously in this chapter.

Approved Chemotherapy Agents for CTCL

Vorinostat 400 mg daily orally was tested in an open-label trial of 74 patients who had progressed on at least two prior systemic therapies. The ORR (skin only) was 29.5%, with 1 CR and 18 PRs. Common adverse events included diarrhea (49%) and fatigue (46%). Grade 3 events were less common but included fatigue (5%), deep venous thromboses/pulmonary emboli (5%), and thrombocytopenia (4%).

Reports from the National Cancer Institute with romidepsin have provided confirmatory results of the use of this class of agent for the treatment of patients with T-cell lymphomas, including some with MF/SS.[248,249] In these reports of several phase I and phase II trials, 10 of 20 patients with MF/SS appeared to have had a PR. Since these studies were published, two clinical trials have been reported demonstrating activity in CTCL. In a large multicenter open-label phase II trial of romidepsin, 96 patients with relapsed stage IB to IVA MF/SS (71% had stage IIB or higher) received standard dosing of 14 mg/m^2, on days 1, 8, and 15 every 28 days.[250] Importantly in these trials, total disease burden, not just skin involvement, was assessed to determine the response rates. The overall response rates was 34%, with 7% of patients achieving a CR. The median response duration was 15 months. Common adverse events included nausea/vomiting in over 56% of patients, asthenia in 44%, and diarrhea in 14%, but again grade 3 toxicities were much less frequent, but also included fatigue in 6%. The HDACI have been linked to cardiac abnormalities and especially arrhythmias. However, in this large trial, events such as cardiac failure, atrioventricular block, and ventricular tachycardia were rare, occurring typically in less than 1% of patients. Avoiding other drugs that may also cause cardiac arrhythmias seems prudent in patients treated with HDACI. The second confirmatory trial was led by investigators at the National Cancer Institute.[251] Seventy-one patients (87% with stage IIB or higher) with heavily pretreated MF/SS (median four prior treatments) were treated with romidepsin at the same dose as described earlier. Again the overall response rate was 34% with 6% CR. Although GI disturbances and fatigue were common in this trial in over 40% of patients, myelosuppression was seen more frequently, with 5% to 10% of patients experiencing grade 3 granulocytopenia and thrombocytopenia. Cardiac arrhythmias were again uncommon, but T-wave/ST changes were seen in the majority of patients, and grade 1 QTc prolongation was seen in 10% of patients.

In general then, toxicity to romidepsin and vorinostat has included alterations in the cardiac conduction that could potentially predispose

to arrhythmias, and treatment of patients has required ongoing telemetry monitoring in some trials, but no evidence for acute or chronic impairment in cardiac function has been noted. Vorinostat demonstrated drug-related grade 1 electrocardiographic changes in five patients and grade 2 in one patient. Therefore it appears safe to use these agents in the outpatient setting with a periodic assessment of cardiac rhythm and QTc interval with an electrocardiogram based on the judgment of the practitioner.

Unfortunately, romidepsin has been shown to be a substrate for the multidrug resistance (MDR) protein (a *p*-glycoprotein) and upregulates the expression of MDR1. Preliminary molecular analyses confirmed the upregulation of MDR1. These data suggest that when resistance to this agent develops, other chemotherapeutic drugs handled by MDR1 may be rendered ineffective. Several patients demonstrated increased surface expression of the CD25 component of the high-affinity IL-2 receptor after treatment. This protein is a target for denileukin diftitox (DD), discussed elsewhere in this chapter as a therapy for MF, suggesting that strategies for combination therapy approaches could be devised to enhance responses to both agents.

Approved Chemotherapy Agents for Cancer But Not for CTCL

Older agents studied previously include alkylating agents like chlorambucil or cisplatin, the microtubule inhibitors etoposide, vincristine, and vinblastine, or the antitumor antibiotics, like bleomycin and doxorubicin.[252-255] In general, the response rates are modest, and duration of response is typically less than 6 months.

McDonald and Bertino[259] reported particularly good results with the antimetabolite methotrexate administered intravenously followed by oral citrovorum factor. Patients received 1 to 5 mg/kg of intravenous methotrexate every 5 days. If a patient tolerated the lowest dose, each subsequent dose was escalated. After five intravenous doses, patients were switched to oral methotrexate (25 to 50 mg) with oral citrovorum as weekly maintenance. All 11 patients achieved "good" or better clearing (>60%) for a median duration of 24 months. Mucositis and skin ulcerations were the most significant toxicity witnessed. Myelosuppression was mild in general. The related compound, trimetrexate has also been reported to be effective in treating CTCL.[257]

As discussed previously, a newer folate analogue, pralatrexate, has also been shown to have substantial activity against PTCL. In early-phase trials several patients with CTCL were felt to benefit, and therefore a trial was designed specifically for MF/SS patients to identify an effective and tolerable dose.[258] Starting with dose de-escalation design at 30 mg/m^2/wk intravenously for 3 of 4 weeks, ultimately 15 mg/m^2/wk was identified as the recommended dosage for further exploration. Twenty-nine patients received this dose for a median of four cycles, and the ORR was 45% (1 CR unconfirmed [CRu]/12 PR). No median response duration had been identified at the time of publication but ranged from 1 day to 372 days. Mucositis (17% grade 3), skin toxicity (7% grade 3), and fatigue (3% grade 3) were common with the use of this agent at the recommended dose. To date no comparison trials of pralatrexate to methotrexate have been performed to assess the relative cost and benefit differences.

Subsequently the benefits of adding 5-fluorouracil to the methotrexate-based regimen, exploiting the synergy between these agents, were evaluated.[259] The methotrexate was administered as a 24-hour continuous infusion at 60 mg/m^2. Immediately after this infusion, 5-flourouracil (20 mg/kg each 24 hours) was continuously infused for 36 to 48 hours. Oral citrovorum factor (10 mg/m^2) was administered intravenously 6 hours after cessation of the methotrexate infusion and then orally for five additional doses. The methotrexate dose was escalated to a maximum of 120 mg/m^2, as allowed by toxicity and response. Ten patients were treated for an average duration of 33 months (range, 3 to 78 months). The number of cycles administered ranged from 5 to 45. All patients achieved a partial remission. Initial cycles were given every 5 to 8 days. Once a good response was achieved, cycles were administered every 3 months as maintenance. Other groups anecdotally reported success with low doses of oral methotrexate. In general these regimens appear to be fairly well tolerated.

The purine antimetabolites have been shown to be active in the treatment of MF/SS. These compounds do not have a single mechanism of action, but all ultimately interfere with intracellular regulation of deoxyribonucleotide pools and this imbalance partially explains the cytotoxicity. This family of drugs includes 2′-deoxycoformycin (DCF), fludarabine phosphate, and 2-chlorodeoxyadenosine (2-CdA).[260]

DCF is a transition-state inhibitor of adenosine deaminase. Inhibition of this enzyme, necessary for the conversion of adenosine to inosine, results in accumulation of 2-deoxy-ATP and subsequent inhibition of the enzyme ribonucleotide diphosphate reductase necessary for DNA synthesis in dividing cells. DCF is also effective against cells in the resting state, where ribonucleotide diphosphate reductase levels are barely detectable. It has been shown that deoxy-ATP accumulation in resting lymphocytes results in increased DNA strand breaks over time; this results in the activation of Ca^{2+}/Mg^{2+}-dependent endonuclease that produces double-stranded DNA strand breaks at internucleosomal regions and also activation of a poly–adenosine diphosphate (ADP)–ribose polymerase that consumes nicotinamide adenine dinucleotide and adenosine triphosphate (ATP). These perturbations lead to apoptotic cell death.

Fludarabine phosphate represents the fluorinated derivative of adenine arabinoside (ara-A). This compound was known to retain cytotoxic action against leukemias and was resistant to degradation by adenosine deaminase. Solubility was poor, however, unless the 5′-monophosphate derivative was used; hence fludarabine monophosphate is the 5′-monophosphate form of F-ara-A. Similar to the mechanism of action of cytarabine or ara-A, fludarabine phosphate requires phosphorylation by deoxycytidine kinase to the active triphosphate metabolite F-ara-ATP. Again, this triphosphate derivative inhibits ribonucleotide reductase, resulting in nucleotide pool imbalances, which prevent DNA repair and ultimately cause apoptosis.

2-CdA represents another chemical modification of deoxyadenosine, which renders the drug resistant to adenosine deaminase. After activation by deoxycytidine kinase, the triphosphate derivative similarly inhibits ribonucleotide reductase and accumulates intracellularly, perturbing the deoxyribonucleotide pool balance, resulting in DNA damage and cell death.

Enzymes such as cytoplasmic 5′-nucleotidase catalyze the degradation of the active triphosphate derivatives discussed earlier. Cells with relatively greater levels of the activation enzymes versus degradation enzymes were identified as likely clinical targets. Lymphoid disorders make good targets for these agents because they contain high levels of deoxycytidine kinase and low levels of 5′-nucleotidase and depend on polymerase-α for DNA repair. Because it was known that T-lymphoblastoid cell lines were most sensitive to these drugs, it was thought that T-lymphocyte disorders would be sensitive in vivo to these agents.

A number of studies treating patients with MF/SS have been performed with these drugs. Table 84-9 shows the results in these studies. Four studies used DCF as a single agent at doses ranging from 3.75 to 10 mg/m^2 daily for three doses every 21 to 28 days.[261-264] Twenty-five patients with MF/SS were included in these studies[261-263]; overall, 3 CRs (12%) and 12 PRs (48%) were documented. The fourth study represents the largest phase II experience reported for the treatment of MF/SS and other CTCLs.[264] Twenty-seven eligible patients were treated for 3 consecutive days at 3.75 mg/m^2/day. Essentially, 80% of the doses in the trial were delivered at 3.75 or 5.0 mg/m^2/day. Twenty-one of 24 response-evaluable patients had SS (14 patients), tumor-stage MF (6 patients), or large cell transformation of MF (1 patient). Patients had failed a median of three prior treatments before enrollment. The overall response rate for patients with MF/SS was 66% (five CRs and nine PRs). Most responses were short-lived because the median duration of response in patients with tumor-stage disease was 2 months (range, 1 to 2 months) and the median duration of response in erythrodermic disease was 3.5 months (no range given, but two patients had responses of at least 17 months).

Table 84-9 Response Rates Observed in Clinical Trials With Purine Antimetabolite Agents

Drug	Overall Response Rate (%)	Reference
DCF	66	119
DCF	100	120
DCF	54	121
DCF	66	122
Fludarabine	18	123
2-CdA	28	124
2-CdA	38	125
2-CdA	18	126
2-CdA	100	127

DCF, 2′-Deoxycoformycin; *2-CdA,* 2-chlorodeoxyadenosine.

The use of fludarabine for the treatment of MF/SS has also been assessed in a single, large phase II trial by Von Hoff et al.[268] They treated 33 patients who were good-risk disease (i.e., no prior systemic therapy) or poor-risk disease (i.e., prior systemic therapy) with fludarabine alone at doses of 25 and 18 mg/m^2 for the two groups, respectively. One complete response and five partial responses were obtained for an overall response rate of 18%.

2-CdA has been evaluated as a single agent for the treatment of MF/SS in 21 patients who had failed at least one prior therapy.[266] There were three CRs and three PRs (overall response rate of 29%). The median duration of response in this heavily pretreated group, however, was only 4 months. Three other groups have also reported results in small numbers of MF patients.[267-269] A total of 21 patients were reported when the studies are pooled. Seven patients achieved responses, giving an overall ORR of 33%, remarkably similar to results from the prior large, single-institution study.

The similarity in mechanism of action of these compounds would suggest that toxicity associated with the various compounds would be similar. This has definitely not been the case, however. There are distinct differences in the spectrum of acute and chronic toxicities with these agents. DCF and fludarabine are associated with higher rates of nausea or vomiting and alopecia than commonly associated with 2-CdA. The most significant toxicities with DCF and fludarabine, however, are neurotoxicity and immunosuppression. Approximately 15% of patients developed sepsis, and 10% developed an opportunistic infection, such as disseminated toxoplasmosis, cytomegalovirus infection, *Pneumocystis carinii* pneumonia, atypical mycobacterial infection, and fungemia in studies. Another 15% developed severe neurotoxicity in the form of confusion, motor weakness, paresthesias, and central nervous system demyelination. Treatment with 2-CdA is extremely well tolerated acutely but may result in somewhat greater myelosuppression than the other agents. This myelosuppression may even be more significant when the agent is used to treat T-lymphocyte disorders as compared to B-cell diseases. In the study by Betticher et al,[270] significant decrements in neutrophils and lymphocyte populations occurred in 46% and 41% of patients, respectively. In a study of 2-CdA, we reduced the days of therapy delivered by continuous infusion to 5 days from the usual 7 because of a perception that the toxicity, primarily prolonged thrombocytopenia, was unacceptable. These results suggest that patients treated with these agents should be carefully evaluated for infectious complications, especially opportunistic infections, and that prophylactic antibiotic therapy should be considered during and after therapy if significant immunosuppression is documented. In addition, one should carefully consider the value of continuing to administer cycles of therapy if there is no evidence of further improvement in clinical response, because of the risk for suddenly developing prolonged cytopenias that may limit future therapeutic approaches. In general it is not apparent that one purine antimetabolite is dramatically superior from these studies, although DCF has a slightly higher overall response rate. It has been observed repeatedly in these studies that occasional patients with SS may have striking and durable responses to treatment, but ideally other agents emerging may allow for higher response rates with less toxicity in this population.

A relatively new class of antineoplastic agents, the proteasome inhibitors, also have activity in CTCL. In vitro activity of bortezomib against CTCL cell lines has been demonstrated, thought to be due to a decrease in NF-κB expression observed, and this reduction resulted in marked increase in spontaneous apoptosis.[270] These data formed the rationale for performing a clinical trial. Zinzani et al[129] reported a small phase II trial of 10 evaluable patients with stage IV or greater MF. In this limited sample, there was one CR and six PR observed, with a range of response durations of 7 to 14 months at the time of the report. Toxicity was as expected, with nearly 20% of patients experiencing grade 3 neutropenia and thrombocytopenia. Additional studies are ongoing with this agent in combination with other agents for histologically aggressive T-cell lymphomas.

Combination chemotherapy has often been employed for MF/SS patients with advanced disease at presentation or with progression. Usually alkylating agents are used, in combination with doxorubicin or vinca alkaloids.[271,272] Response rates of 80% to 100% have been achieved, with longer durations of remission than observed with single-agent therapy. There have been no trials comparing different aggressive combination regimens. High response rates with perhaps less toxicity have been observed in treating other NHLs using infusional combination regimens such as etoposide, prednisone, vincristine (Oncovin), cyclophosphamide, and hydroxydaunomycin (EPOCH). A trial in CTCL suggested comparable activity to a bolus schedule, with greater risk for febrile neutropenia and bacteremia associated with indwelling catheters required for the infusion.[273]

It is our philosophy that this disease behaves similarly to other low-grade lymphomas (e.g., B-cell type), with periods of remission becoming shorter with subsequent therapeutic interventions. However, as noted, advanced-stage MF is associated with a relatively short median life expectancy. Patients with significant nodal involvement or extensive skin disease (T4 in particular) have median life expectancies of 30 to 55 months.[200] A driving force in the development of treatments for this disease is the goal of altering the natural history for this group of poor-prognosis patients, or for delaying the development of poor-prognosis disease. There is no clinical trial of any modality that has demonstrated a survival benefit as compared with a control group. Kaye et al[204] demonstrated more than a decade ago that combination chemotherapy (and total-skin electron beam radiation therapy) did not provide a more favorable survival or even clinically significant delays in time to recurrence for patients, compared with standard palliative, less-aggressive therapies. New drugs or approaches are still being developed with the goal of altering the disease state in poor-prognosis patients.

Because of the pressing need to identify new strategies to provide more durable remissions or even curative therapy for advanced CTCL, new drugs continue to be tested. On the basis of the clinical evidence of possible activity in early-phase testing, several drugs have been evaluated. In a phase II trial of 44 patients with relapsed MF or PTCL (unspecified), a dose of gemcitabine was administered at 1200 mg/m^2 over 30 minutes for 3 weeks every 28 days.[274] There were 5 (11%) CRs and 26 (59%) PRs (overall response rate 70.5%). The median duration of response ranged from 15 months for CRs to 10 months for those patients with PR. There appeared to be no difference in response type between patients with MF and PTCL. In a second trial at the MD Anderson Cancer Center with gemcitabine administered similarly but at a dose of 1000 mg/m^2, investigators documented a 68% overall response rate (17/25), with two patients developing a CR.[275] Toxicity included myelosuppression in the majority of patients and development of a hemolytic uremic syndrome in two older adult patients. Most recently gemcitabine was studied as a

first-line systemic treatment in 27 patients with stage T3 or T4 MF/SS.[276] The overall response rate was 70% (19/27), with six CRs. The median time to progression was 10 months. Toxicity was generally mild.

The camptothecins are a family of compounds that inhibit topoisomerase I, an enzyme required for unwinding strands of DNA for transcription and replication. In early-phase studies it was recognized that the administration of 9-aminocamptothecin (9-AC) by continuous infusion to maintain a drug concentration above a threshold level coupled with duration of exposure was important to ensure adequate inhibition of the target enzyme. In these studies at appropriate concentrations, activity was identified in NHLs,[277] and it was therefore appropriate to study in MF/SS. We undertook a trial of intravenous 9-AC in patients with MF/SS.[278] The trial was prematurely closed after 12 patients received 30 cycles. There were 2 PRs (17%) in a heavily pretreated population of patients; however, 6 of the 12 patients (50%) developed indwelling catheter infections, and 3 patients died 4 to 8 weeks after the last dose of 9-AC. The toxicity was deemed too excessive to justify this dose, route, and schedule of administration. This study nicely demonstrates the hazards of chemotherapy in this patient population, including the underlying risk for infection and the relative contraindication to indwelling catheters (hence a bias toward agents administered as short infusions through peripheral catheters, or oral agents, and the importance of prophylactic antibiotics if excessive invasive procedures are anticipated).

Another drug empirically tested for the treatment of MF/SS is pegylated doxorubicin based on the historic activity of doxorubicin against NHLs. The process of encapsulating the doxorubicin in pegylated liposomes creates stable, long circulating carriers of the drug that result in greater tumor cell uptake versus normal cell uptake. This may reduce normal cardiotoxicity and myelosuppression. The drug is approved for use against Kaposi sarcoma but has been evaluated in a small group of patients with MF in Europe. Six patients in this pilot study received pegylated liposomal doxorubicin at 20 mg/m^2 every 4 weeks.[279] Four patients achieved a CR and one other patient achieved a partial remission. The overall response rate was 83%. The median duration of response was not reported. Grade 3 adverse events were few and included one patient with lymphopenia and two with anemia. No other severe adverse effects were noted. A larger retrospective multicenter report of this agent administered intravenously at 20 to 40 mg/m^2 every 2 to 3 weeks in 34 patients has also been conducted.[280] Overall, 15 patients achieved a CR and 15 achieved a PR (response rate of 88%), with EFS of 12 months. Toxicity was similarly manageable.

The ability to biopsy skin lesions for studies of tumor cells in MF/SS has resulted in this disease being a favorable setting for the evaluation of candidate therapeutic agents and exploration of rational therapeutic development. The knowledge gained regarding the human genome and the new studies of proteomics are increasingly allowing investigators to test new drugs at appropriate dosages, by correct schedule of administration, and to generate, prove, or refute hypotheses regarding mechanism of action or resistance. A number of studies of such agents have recently been completed and may lead to further drug testing in search of enhanced therapeutic activity in MF or perhaps achieve cure of MF.

An example of such an achievement has been the work with temozolomide for the treatment of MF/SS. This agent is an oral imidazotetrazine that has shown activity in solid tumors, such as brain tumors and melanoma. It has been determined that mechanisms of resistance to this agent include expression of high levels of the scavenger protein O^6-alkylguanine-DNA alkyltransferase (AGT) in tumor cells. This protein is implicated in the recognition and repair of alkylator-induced DNA damage introduced by chloroethylnitrosourea (e.g., bis-chloroethylnitrosourea or BCNU) or methylating agents (temozolomide).[281] The presence of the AGT protein imparts resistance by removing toxic lesions formed at the O^6 position of guanine. Chloroethylnitrosourea cross-links are prevented from forming by the removal of the chloroethyl lesion from the O^6 position before rearrangement or by the reaction with the intermediate, 1,O^6-ethanoguanine, to form a cross-link between DNA and the repair protein. The AGT protein is inactivated in the process.[282] Studies evaluating AGT levels in patients with brain tumors receiving BCNU therapy support the role of AGT in resistance to chloroethylating and methylating agents. Retrospective and prospective human studies have demonstrated a correlation between AGT concentration and clinical outcome after treatment with BCNU.[283]

Because of the unique sensitivity of MF to topical BCNU, we were interested in exploring levels of AGT in a variety of patients with various stages of MF/SS. Patients with patch or plaque lesions expressed low levels of the AGT protein compared with a number of controls with reactive dermatitis, and the level of AGT increased correlating with the stage of MF/SS (i.e., patients with malignant lymphocytes harvested from peripheral blood or involved lymph nodes had higher levels of AGT than those with patch or plaque lesions).[284] Given this data, we initiated a prospective trial of temozolomide in relapsed patients with MF/SS, correlating response to levels of AGT and other known resistance proteins (such as the family DNA mismatch repair proteins).

Twenty-six patients with relapsed heavily pretreated stage IB-IVB disease were evaluated.[285] The overall response rate was 27% with two complete responders. Median disease-free survival was 4 months. We hypothesized that the optimal phenotype that would predict for good response to therapy would be low levels of AGT combined with normal levels of several DNA mismatch repair proteins. Interestingly, hypermethylation of these DNA repair proteins has been reported to result in silencing of the genes and to correlate with lack of the proteins as assessed by immunohistochemical techniques in patients with MF.[286] This hypermethylation may be more prevalent in more advanced tumor lesions and suggests that a propensity for mutations may precede clinical progression. It also suggests that patients might benefit from treatment with a demethylating agent in combination with temozolomide. Unfortunately, in the trial above, pretreatment levels of O^6-methylguanine-DNA methyltransferase (MGMT) and the mismatch repair genes mutL homolog 1 (MLH1)/mutS homolog 2 (MSH2) were not predictive of response to the temozolomide.

Role of Stem Cell Transplantation

The natural evolution of the use of chemotherapy for this disease has been to use dose-intensified approaches with hematopoietic reconstitution with autologous[287] or allogeneic bone marrow or stem cells.[288] There are few reports in the literature of such treatment programs in well-designed prospective clinical trials.

Given the propensity of Sézary cells to be detectable despite a lack of clinical evidence even in early-stage disease if sophisticated molecular techniques are used, it is likely that reinfusion of neoplastic cells may occur with autologous bone marrow transplantation. The lack of dramatic benefit in low-grade B-cell lymphomas for autologous bone marrow transplantation similarly suggests that this approach will not benefit patients. We had a very limited experience with autologous bone marrow and SCT at our center and abandoned it, because of rapid progression of disease, in favor of allogeneic SCT.

Allogeneic SCT has been presumed to be curative in small percentages of patients with low-grade B-cell lymphomas, and this approach has now been investigated in the small subset of young MF/SS patients with HLA-identical siblings or HLA-matched unrelated donors who have poor-prognosis disease and have demonstrated relapse or resistance to interferons, chemotherapy, and topical therapies. In an early study, a single patient treated with cyclophosphamide and total body irradiation was reported to achieve complete remission after allogeneic SCT, but relapse occurred by day 70, necessitating additional therapy.[289] The patient remained in complete remission and was alive at least 6 years after the transplantation. In light of this, we and others have begun to explore this approach in patients with MF/SS who are young and have matched donors available.[290] We have used marrow-derived stem cells enriched with peripheral blood–derived stem cells or peripheral blood stem cells only. We believe that

in appropriate patients this approach should continue to be explored; older patients may benefit from strategies involving the use of RIC regimens that involve less myeloablative preparative regimens and rely on the effects of the donor marrow to create a graft-versus-lymphoma effect for disease control. Molina et al[294] reported promising data using allogeneic SCT for patients with refractory MF/SS. Each of the seven patients treated had failed a median of seven therapies. Although one patient received a myeloablative conditioning regimen, five received a reduced-intensity regimen consisting of fludarabine and melphalan. Each of the patients achieved a clinical remission and resolution of molecular and cytogenetic evidence of the disease. After a median follow-up of 56 months, six of the eight patients were alive and free of evidence of lymphoma. The other two patients died of transplant-related complications. This small study provided the impetus to further develop allogeneic SCT strategies for the treatment of advanced CTCL refractory to standard therapies at many centers.

A metaanalysis from reports before 2008 of 20 allogeneic and 19 ASCTs was reported by Wu et al[295]and includes some of the patients described here. The majority of patients in both groups received myeloablative chemotherapy and total-skin electron beam as preparative regimens, with the remainder in the allogeneic SCT group receiving RIC regimens. In the ASCT group event-free survival was only 20% at 1 year and 0% at 5 years, statistically significantly less the 65% and 60%, respectively, in the allogeneic SCT group. Overall survival was also significantly better in the allogeneic SCT group, confirming our impressions regarding the limitations of ASCT for this disease.

Since this metaanalysis was published, two larger single-institution or multiinstitution reports have been published. A European group reported the outcomes on 60 patients with MF/SS (36/24) who received either a matched related donor (mRD) or matched unrelated donor (mUD) (45/15) allogeneic SCT.[293] Survival at 3 years was 54%. A multivariate analysis suggested that recipients of mRD SCT had better progression-free and overall survival than patients receiving mUD SCT transplants, and reduced-intensity transplants had less nonrelapse mortality without increased relapse of disease.

A single-institution trial in the United States reported the outcome of 19 patients treated with total-skin electron beam and nonmyeloablative allogeneic SCT in advanced MF/SS.[294] The complete response rate was 58%. Relapse was sometimes treated with reduced immunosuppression or donor lymphocyte infusions. With a median follow-up of 19 months, the median overall survival had not been reached.

Other Established Treatments for CTCL

Extracorporeal Photopheresis

An adaptation of the use of psoralen with UVA called extracorporeal photopheresis has been described by Edelson et al.[298] Patients ingest 0.6 mg/kg of oral 8-methoxypsoralen before a treatment. The treatment consists of routine leukapheresis with isolation of the mononuclear cell fraction. The cells are then exposed to UVA ex vivo within a special chamber inside the pheresis device. In the initial report, Edelson et al documented an 88.5% loss of lymphocyte viability compared with control patients treated with the drug alone. Overall, 64% of patients responded to therapy, with the best results in those with generalized erythroderma and, presumably, higher circulating Sézary cell levels. The mechanism is not thought to be directly cytotoxic, but rather to induce a host immune response to the reinfused altered Sézary cells, possibly through activation of circulating dendritic cells.[296] This theory would explain the findings of some investigators that patients without leukemic involvement do poorly with such therapy. This treatment modality has resulted in the best results in SS patients with erythroderma of short duration and with adequate $CD8^+$ blood counts.

Several other groups have reported their experiences with photopheresis.[297,298] When the data are analyzed on an intent-to-treat basis, overall response rates of 36% to 52% were observed. Only 12% to 18% achieved CR. These investigators attempted to wean patients from therapy as clearing of lesions was documented. Ultimately, most responders developed recurrent disease. Many trials are under way combining extracorporeal photopheresis with other active modalities.

Toxicity is mild and includes occasional nausea, erythematous flares, and temperature elevations. Patients may develop hypotension during leukapheresis, which usually responds to saline infusions.

Interferons

Interferon-α is an active agent for the treatment of MF.[299-303] Dosages and routes of administration have differed among studies. Initially, high-dose interferon was used, with maximum doses of 36 to 50 million International Units. Bunn et al[302,303] and Olsen et al[300] independently demonstrated complete response rates of 10% to 27% in heavily pretreated patients. The duration of response was only 5.5 months. Later trials of untreated patients with doses of 3 to 18 million International Units given subcutaneously daily have demonstrated response rates of 80% to 92%. From all these studies, it appears that a reasonable and tolerable single-agent dose is 12 million International Units/m^2 administered subcutaneously daily. We recommend starting at 3 million International Units and gradually increasing as treatment is tolerated by the patient.

In a single trial, the results of treatment of 16 refractory CTCL patients with interferon-γ were reported.[304] Five patients experienced PRs (response rate 31%) with a median duration of 10 months (range, 3 to 32+ months).

Side effects of all interferons are dose dependent. Most common adverse effects are constitutional symptoms, consisting of fever, chills, myalgias, malaise, and anorexia. Rarely, cytopenias, elevations of liver function test results, renal dysfunction, cardiac dysfunction, or changes in mental status can be seen. Patients need to be monitored closely while on interferon.

Retinoids

Vitamin A and its natural and synthetic analogues are known as retinoids. These compounds have diverse biologic effects, influencing differentiation and proliferation of a number of structures during development.[305] In addition, some compounds have been shown to influence immune function.[306,307] Clinically, a number of approved formulations have demonstrated efficacy in MF and SS.

Many of the trials of retinoids for MF/SS were performed decades ago with limited patient numbers. Treatment with isotretinoin (13-cis-retinoic acid), a nonaromatic retinoid, has been associated with clinical benefit in a number of trials. Overall objective responses have been described in 33 of 56 patients treated in three clinical trials.[308-310] A monoaromatic retinoid compound, etretinate, did not achieve similar results when tested as monotherapy for MF in several trials[311-317] but did show efficacy in a trial for the treatment of parapsoriasis en plaques.[315] A polyaromatic retinoid demonstrated efficacy in a small trial. Objective responses were observed in three of six patients (one CR and two PRs).

Vitamin A Derivatives Not Approved for CTCL

There has been a resurgence of interest in retinoids for the treatment of hematologic malignancies with the approval of all-trans retinoic acid (ATRA) for acute promyelocytic leukemia. The mechanism of biologic effect for retinoids is better understood given the advances in basic sciences over the past decades. ATRA has been studied in 33 patients with relapsed MF who had not had prior exposure to oral retinoids.[313] Patients received 45 mg/m^2 daily in two divided doses for up to 2 years. In 29 evaluable patients, 5 responses were observed (1 CR, 4 PRs) for an ORR of 17% with a median duration of response of 4.5 months. Another seven patients (24%) had stable disease. The

most common toxicities included headache (37%) and mucous membrane dryness (80%). Only one patient experienced severe elevation of lipid levels. ATRA works through binding to specific retinoic acid receptors (RAR family α, β, and γ), which then bind to retinoic acid response elements located upstream of gene promoters, providing transcriptional control of proteins.

Approved Vitamin A Derivatives for CTCL

A second family of receptors, the retinoid X family of receptors (RXR), has been identified.[312,313] Bexarotene is a synthetic retinoid that selectively binds this family of receptors. Unfortunately, as is the case with the retinoids that bind the RAR family of receptors, it is not known ultimately the expression of which genes is altered to achieve the clinical benefits observed. This compound has been tested in separate trials of early- and advanced-stage patients. At the 300 mg/m^2 dosage daily (dose recommended by the FDA), 54% of the 94 advanced-stage patients in an open-label phase II study responded to therapy (2% CRs).[313] The median duration of response was 299 days. The early disease trial showed similar response rates. The toxicity spectrum is somewhat different from the RAR-specific retinoids, including more frequent severe elevations of lipid levels (although rarely associated with pancreatitis), hypothyroidism, and less frequent headaches and dry mucous membranes. The compound can also be used topically. A phase I/II trial of the topical bexarotene demonstrated a 63% response rate (21% clinical CRs) in primarily early-stage patients with lesional application.[312] Toxicity was mostly local irritation with erythema.

The favorable toxicity profile has led to a number of combination-modality trials using retinoids. Some of these small trials have combined retinoids with interferon-α and have reported response rates of 40% to 50%. Combinations of retinoids with PUVA have been suggested to result in clinical benefit in less time with less exposure to ultraviolet radiation. These experiences have been generally limited and often uncontrolled, making definitive conclusions impossible. Larger randomized trials would be needed to determine if routine use of such combinations should be undertaken off of an investigational trial except in rare cases.

Monoclonal Antibodies

Targeted therapy has become a reality for the treatment of many types of cancer, including MF/SS. Although the most common approach has been with the use of antibodies that target antigens expressed by the tumor cells (e.g., rituximab), another class of compounds known as recombinant fusion proteins has been developed, the prototype being DD, for the treatment of CTCL.

Approved Monoclonal Antibodies for Cutaneous T-Cell Lymphoma

DD is a single-chain protein in which the receptor-binding domain of native diphtheria toxin is replaced by the sequences encoding the IL-2 gene (CD25).[316] Once this molecule binds to the high-affinity IL-2 receptor, the fusion toxin is internalized by receptor-mediated endocytosis and is proteolytically cleaved within endosomes to liberate the free ADP-ribosyl transferase activity of diphtheria toxin into the cytosol, where it then inhibits protein synthesis.[314,318]

In early phase I studies with DD, the response rate of CTCL patients who demonstrated at least 20% expression of the IL-2 receptor was 30%.[319] A phase III study comparing various dose levels of DD demonstrated a similar response rate, but there was significant toxicity that led to a high drop-out rate (constitutional symptoms, infusional reactions such as hypotension, chest pain or dyspnea, and a vascular leak syndrome).[320] Based on this trial the drug was approved for the treatment of relapsed/refractory CD25-expressing CTCL.

Recently two dose levels of DD were compared to placebo in patients with stage IA to III disease.[321] This clinical trial is one of the larger studies conducted in MF/SS to date and provides interesting information because it is one of the few to include a placebo control arm. Overall 144 patients were enrolled, all with 20% or higher expression of CD25 on a skin biopsy specimen and randomized in a 1:1:1 fashion to either 18 mcg/kg DD, 9 mcg/kg DD, or the placebo with the primary end point being overall response rate. The response rates were 49.1%, 37.85%, and 15.9%, respectively, and both DD dose arms were statistically superior to the placebo. PFS (median >2 years) in the DD arms was also superior compared with placebo (median 4 months). Moderately severe and severe adverse events were both greater in the DD arms than placebo, but there was no dose effect with regard to safety.

Because of the toxicity spectrum of DD, we limit the use of this agent to patients who have failed several systemic agents (often bexarotene and interferon) previously and have more threatening disease such as the presence of skin tumors or nodal involvement. It is important to note that the pivotal trials did not allow concomitant use of corticosteroids to prevent nausea and infusional reactions. Subsequently a retrospective case review of patients pretreated with corticosteroids suggested a more favorable toxicity profile and a response rate of nearly 60%.[322] The nature of the trial limits the conclusions to be drawn but suggests that aggressive pretreatment with steroids can make this drug a useful addition to treat patients with advanced relapsed MF.

Approved Targeted Agents for Cancer But Not for Cutaneous T-Cell Lymphoma

Targeted therapies against unique tumor antigens continue to be tested, such as the monoclonal antibody alemtuzumab. This antibody is directed against CD52 and presumably works through antibody-dependent cellular cytotoxicity and activation of complement-dependent cytolysis[323-326] but may also induce apoptosis without complement activation. A number of trials of this agent in various stages of MF/SS have been reported. The initial phase II study using alemtuzumab in 50 patients with low-grade NHL, including 8 patients with MF, demonstrated a 50% response rate in MF (4 of 8 patients, 2 CR).[327] In a phase II multicenter study of 22 patients with advanced MF (n = 15) and SS (n = 7) refractory to PUVA, radiotherapy, or systemic chemotherapy, intravenous treatment with 30 mg alemtuzumab three times a week for 12 weeks resulted in an ORR of 55%, with 32% of patients in CR and 23% in PR.[328] Higher response rates were demonstrated in patients with erythroderma and those with fewer previous treatment regimens. Both patients with tumor-stage disease had progressive disease on alemtuzumab. Kennedy et al[332] studied the efficacy of alemtuzumab in CTCL patients (stage IIB to IV) and demonstrated a PR in three (38%) with infectious complications in seven of eight patients. Two of the responders had SS, and these findings support our perspective that alemtuzumab may be most helpful in patients with erythrodermic MF and SS. Therefore we conducted a trial in 19 heavily pretreated patients with erythrodermic MF or frank SS. In this trial the patients received a variety of subcutaneous, intravenous, or both routes of administration. The overall response rate was 84% (47% CR and 37% PR). Median PFS was 6 months, but median overall survival was 41 months despite the advanced-stage disease and extensive prior therapy. We did not experience the dramatic infectious or cardiac events some investigators have reported, likely because of the routine inclusion of prophylactic antiviral, antifungal, and antipneumocystis agents.[330]

Another target of therapy for MF/SS is CD30. As noted earlier, this antigen is expressed in a variety of malignancies, including advanced HL, ALCL, and often the lesions of tumor-stage or transformed MF. As previously discussed, brentuximab vedotin (SGN-35), is an antibody to CD30 conjugated to a derivative of auristatin E (monomethyl auristatin E), which inhibits microtubules and induces apoptosis in target cells. It has been approved for the treatment of relapsed HL and systemic ALCL that express CD30. There are now efforts under way to determine its efficacy in primary cutaneous ALCL and MF. Several studies have been reported in a preliminary fashion. Recently, investigators at Stanford led a trial of this molecule in MF/SS with all levels of expression of CD30.[331] At the time of the

preliminary report, 15 patients with MF/SS (13 stage IIB to IV MF/SS, 9 with large cell transformation) were included. Seven of the patients had less than 10% CD30 expression, 7 had 10% to 50% expression, and 1 had more than 50% expression by immunohistochemical analysis. An objective response was observed in 60% of the patients and in all cohorts by expression level of CD30. Toxicity was generally mild, including fatigue, peripheral neuropathy, rash, and infusion reactions. Two patients with pretreatment expression of CD30 developed antigen loss during treatment. Definitive trials to determine its efficacy in MF/SS and cutaneous ALCL are planned.

Investigational Approaches

Because of the chronic relapsing nature of MF, new therapies with different mechanisms of action are needed to circumvent tumor resistance. A variety of such approaches are under investigation. These include the use of existing or newly developed retinoid compounds or combinations of retinoids with other agents.[332] Other combination modalities under study include retinoids, interferons, and chemotherapy or radiation therapy[333] and total-skin electron beam radiotherapy followed by photopheresis or chemotherapy.[334] Given the lack of benefits of combination chemotherapy and radiotherapy previously, the role of such approaches should remain investigational. Another less toxic combination approach has been the simultaneous administration of interferon and phototherapy.[335] An overall response rate of 92% has been observed with this combination in all stages of patients, many of whom had been previously treated with other therapies.

Another approach to the therapy of this disease has involved new drugs to exploit the biologic characteristics of these neoplastic cells. For example, Notch signaling has been shown to be dysregulated in a variety of T-lymphocyte neoplasms. It has also been shown that Notch1 is expressed in tumor cells in many advanced-stage patients with MF/SS.[146] There are specific inhibitors of Notch signaling that induce apoptosis in MF/SS cell lines, and this is an elegant example of how these molecular breakthroughs could be exploited to develop new approaches to the treatment of this disease.

Knowledge of the unique cytokine milieu associated with these neoplastic T cells has led to trials testing cytokines that may inhibit the growth of these cells, such as IL-12[335] or IL-2.[336] Vaccine approaches may be practical.

Significant amounts of basic and practical research have been performed in an attempt to control this disease, and future treatment approaches will likely depend on further understanding of the molecular and genetic bases of these disorders. We hope that one of the strategies under development or study will lead to treatments that can control the disease and symptomatic effects or even cure this neoplasm in the majority of afflicted patients.

CHAPTER 85

PLASMA CELL NEOPLASMS

Nikhil C. Munshi and Sundar Jagannath

Multiple myeloma (MM) is a malignancy involving terminally differentiated plasma cells. It includes a spectrum of plasma cell disorders ranging from monoclonal gammopathy of unknown significance (MGUS), a relatively benign condition, to smoldering MM (SMM), the symptomatic malignant disorder MM and its more aggressive form, plasma cell leukemia with circulating myeloma cells in the blood. Various other plasma cell disorders belong to the same group of conditions, including Castleman disease, α heavy-chain disease, and Waldenström macroglobulinemia. MM is characterized by the presence of clonal plasma cells, and production in the majority of cases of a monoclonal immunoglobulin or its fragment with subsequent involvement or effects on organ function. There are five classes of immunoglobulins, and the dysfunctional plasma cells can produce any one of the five immunoglobulin subtypes, including immunoglobulin G (IgG), IgA, IgM, IgD, and IgE. Infrequently, heavy-chain components of the immunoglobulin are not produced by the myeloma cells, and the disease manifests as production and secretion of light chain only, which would either be κ or λ type. Very rarely, myeloma fails to produce any significant amount of protein and manifests as a nonsecretory MM. With more recently available free high-sensitivity, free light-chain testing, the frequency of true nonsecretory MM has significantly decreased.

EPIDEMIOLOGY

Multiple myeloma accounts for 1% of all malignancies and is the second most common hematologic malignancy with prevalence of around 10%. The prevalence of MM was around 64,615 in 2008, and it is estimated that 20,520 men and women (11,400 men and 9120 women) will be diagnosed with and 10,610 men and women will die of myeloma in 2011. It is a disease involving a relatively older population with a median age at diagnosis of 69 years and median age at death of 74 years (Fig. 85-1, A). Fewer than 5% of patients at diagnosis are younger than age 40 years. Myeloma is more frequent in men than women and in African Americans as opposed to whites in the United States (Fig. 85-1, *B*). The incidence of MM in black men is approximately 14.5 per 100,000 per year compared with 10.2 per 100,000 per year in black women. The corresponding incidence is 7.2 and 4.6 per 100,000 in white men and women, respectively. Although the Asian population has a lower incidence of myeloma compared with their white counterparts, ethnic groups, including Hawaiians, female Hispanics, female American Indians from New Mexico, and Alaskan natives, experience higher incidence rates than those of the U.S. white population from the same geographic regions. Although there has been some increase in the incidence of MM, it is primarily attributed to better detection and surveillance for the disease as well as overall aging of the population worldwide. Moreover, there has been improvement in overall survival (OS) times for patients with MM from 3 to 7 years and longer.

HISTORICAL ASPECTS

The first published clinical description of a patient with myeloma was made by Dr. Henry Bence Jones in 1850 describing a patient, Thomas Alexander McBean, who presented with symptoms of fatigue, diffuse bone pain, and urinary frequency. Urinalysis showed a urinary protein with a peculiar heat property (now called *Bence Jones proteins*). The disease was, however, given the name MM by Rustizky in 1873 after his observation of multiple bone lesions in a similar patient. A larger review of this disease by Kahler in 1889 also led to it being called Kahler disease, especially in Europe. Subsequently, investigative advances defined the disease further with descriptions of plasma cell and radiographic abnormalities in 1900 by Wright, bone marrow (BM) aspiration in 1929, electrophoresis in 1937, and immunoelectrophoresis identifying the heavy and light chains in 1953, confirming the monoclonality of immunoglobulins in this disease. In recent years, recurrent chromosomal translocations have defined subgroups of myeloma patients, and gene expression profiling and proteomic studies are providing a greater molecular understanding of the disease. Similarly, the influence of the BM microenvironment on myeloma cell growth and survival has been explored and led to the identification of novel therapeutic targets. The first randomized study in myeloma compared urethane with placebo and indicated that the survival of patients receiving urethane was inferior to that observed with a placebo.

Progress in myeloma therapy started with the first successful use of a chemotherapeutic agent in myeloma with racemic mixture of D- and L-phenylalanine mustards (Sarcolysine) in 1958 by Blokhin and colleagues; use of melphalan in 1962 by Bergsagel and colleagues; use of high doses of glucocorticoids in 1967; and subsequent use of melphalan in combination with prednisone, which is used even today. With the use of high-dose therapy (HDT) with melphalan by McElwain and Powles in 1983, complete remissions (CRs) were achieved in a proportion of patients, and the identification of novel agents such as thalidomide and its immunomodulatory analogue lenalidomide and the proteasome inhibitor bortezomib during the past 10 years targeting both myeloma cells as well as the BM microenvironment have further improved responses and OS.

PATHOBIOLOGY

Multiple myeloma, as with a number of other malignancies, remains a disease that is initiated and sustained by genomic changes that provide uncontrolled proliferative advantages to the tumor cells. Myeloma represents the classic multistep transformation process with an initial premalignant stage, MGUS, demonstrating a number of recurrent cytogenetic abnormalities as well as gene expression changes (Table 85-1). It has been now well documented that all MM develops from MGUS, suggesting that the initial event required for transformation to MGUS provides the first step in a multistep process.[1]

Cytogenetics

Multiple myeloma is characterized by a significant molecular and genomic heterogeneity affecting tumor clones. Karyotypes in MM are usually complex, with both number and structural abnormalities in chromosome observed (Fig. 85-2).[2] Although chromosomal abnormalities using conventional cytogenetics in newly-diagnosed patients

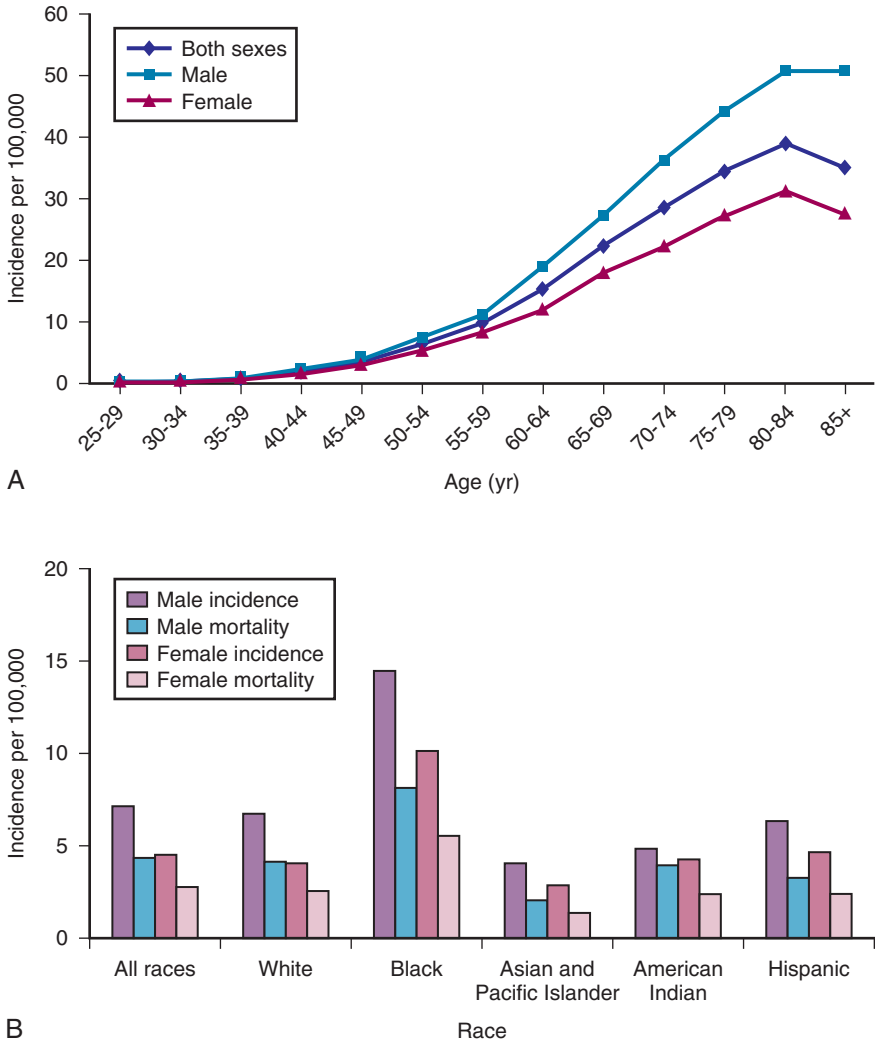

Figure 85-1 A, Multiple myeloma (MM) average annual age- and gender-specific incidence per 100,000 population in the United States in 2009. **B,** MM average annual race-specific incidence per 100,000 population in the United States in 2009. An increase in incidence is noted with advancing age, men are affected more than women, and a higher incidence is observed in blacks than whites.

Table 85-1 Recurrent Cytogenetic Changes in Myeloma

Common Cytogenetic Alterations		
Chromosomal Abnormality	**Frequency (% patients)**	**Genes Involved**
Hyperdiploidy	50-60	Unclear
Hypodiploid	20	Unclear
Pseudodiploid	15	Unclear
del(17p)	8	p53
t(4:14):	15	FGFR3, MMSET
t(11;14):	20	cyclin D1
t(14;16):	3	c-maf
t(14;20)	1	maf-b
t(6p25 or 6p21;14)	1	IRF-4 or CCND3
t(8;14)	5	c-myc
t(9;14)	<1	PAX-5
del(13) or (13q)	50	unclear
Recently Identified Alterations		
1q+:		35%
1p-:		30%
5q+:		50%
12p-:		10%

are detected in only 30-50% of patients due to the low proliferative activity of MM cells, in advanced stages when cells usually have a higher proliferative index, a greater number of abnormalities are identified. Importantly, using fluorescent in situ hybridization (FISH) as well as flow cytometry–based DNA aneuploidy analysis, genomic alterations are observed in more than 90% of the patients with MM. These results suggest that the normal cytogenetics observed in the majority of the patients is derived from normal cellular components of the BM and not from the cells belonging to the myeloma clone. Although detection of karyotypic changes in MGUS and SMM is extremely low, again because of the very low frequency of proliferating cells in these indolent conditions, using FISH shows that up to 50% of the patients with MGUS and SMM have genomic alterations.

In a study of 542 patients, gain, loss, or translocations involving the p or q arm of every single chromosome has been described in MM. Despite this complexity, several recurrent changes are observed. The most prominent amongst them is hyperdiploidy, which commonly involves gains of the whole chromosome 3, 5, 7, 9, 11, 15, 19, or 21. Additional recurrent abnormalities include loss of chromosome 13, t(4;14)(p16;q32), t(11;14)(q13;q32), or t(14;16)(q23;q32). The common chromosomal region involved in these translocations is 14q32 region, which contains the IgH gene, suggesting that this abnormality may be an early important event in the development of plasma cell disorders. This has been confirmed using FISH analysis of interphase cells showing its involvement in approximately 47% of MGUS patients and more than 70% of patients with MM. In other patients, translocation partners involve the λ light-chain region on chromosome 22. This abnormality is observed in 17% of patients

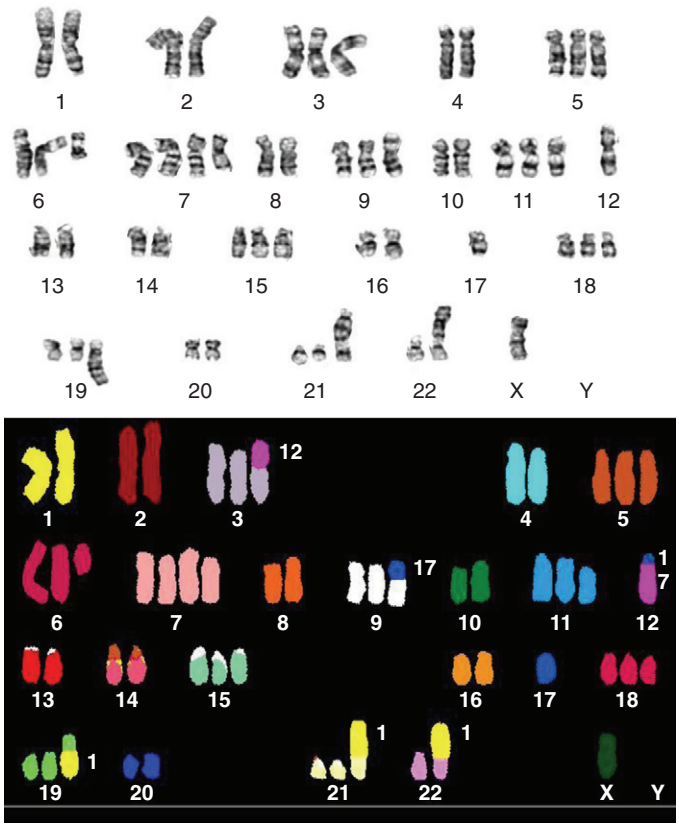

Figure 85-2 A SPECTRAL KARYOTYPE SHOWING SIGNIFICANT KARYOTYPIC ABNORMALITIES IN A PATIENT WITH MYELOMA. *(Courtesy J.R. Sawyer.)*

with MM. Translocations involving the κ light-chain genes on chromosome 2 are rare. The frequency of various common translocations in MM is provided in Table 85-1.

Hyperdiploidy

Almost half of MM patients have a hyperdiploid karyotype (>46 chromosomes), and fewer than one-quarter of the patients have a hypodiploid karyotype (<46 chromosomes). Hyperdiploid MM is a relatively homogeneous group with median quartile of 54 chromosomes involving nonrandom gains. Interestingly, trisomies mostly involve odd-numbered chromosomes, 3, 5, 7, 9, 11, 15, 19, and 21. The structural abnormalities observed in MM are not exclusive for nonhyperdiploid MM because they are also observed in hyperdiploid patients along with the hyperdiploid changes. Of note, most (if not all) of the human myeloma cell lines are derived from patients with the nonhyperdiploid genomic changes, which may reflect the difference in proliferative potential between these two categories. Hyperdiploidy has been reported to be associated with a better prognosis based on retrospective analyses. This has been confirmed more recently using interphase FISH approach to define ploidy. However, a study by the International Myeloma Foundation (IFM) showed that hyperdiploidy was not an independent prognostic factor but was associated with a lower incidence of other independent poor risk features such as del(13), t(4;14), and del(17p).[3]

Translocations Involving 14q32

Chromosomal region 14q32 has been identified as a recurrent site of translocations in myeloma. Unlike mantle cell lymphoma, in which the IgH breakpoint is near the site targeted by VDJ recombination, the breakpoint on14q32 in MM is located within the IgH or the switch region. This suggests that the translocations are caused by either somatic hypermutation or switch recombination. In all, more than 25 different chromosomal regions have been involved in translocations involving 14q32 region; the major translocation partners involving this IgH gene location are 4p16, 6p21, 11q13, and 16q23. The t(11;14)(q13;q32) translocation is present in approximately 20% of myeloma patients and involves the cyclin D1 gene.[4] Although this translocation leads to upregulation of cyclin D1, its role in oncogenesis is unknown. Despite known molecular functions of cyclin D1 in cell cycle and proliferation, the t(11;14) myelomas have a low proliferative index, appearing morphologically as small mature plasma cells or lymphoplasmacytic cells expressing CD20. Initial studies suggested a better survival outcome in patients with this translocation; however, larger studies have failed to confirm this observation.

The t(4;14)(p16;q32) is a cryptic translocation not easily detectable by conventional karyotyping. It leads to a unique dysregulation of two genes located at 4p16 region, the gene for the fibroblast growth factors 3 (FGFR3) located on the telomeric side of the breakpoint and MM SET domain (MMSET) located on the centromeric side. The translocation leads to the molecular activation of FGFR3 gene transcription. FGFR3 is one of the four high-affinity tyrosine kinase receptors for FGF. FGFR-mediated signaling results in signal transducer and activator of transcription 3 (STAT3) phosphorylation and activation of the mitogen-activated protein kinase (MAPK) pathway. It is not expressed in normal plasma cells and is shown to have oncogenic potential both in vitro and in vivo studies. Interestingly, about one-third of the patients with t(4;14) do not overexpress FGFR3. The translocation also generates a novel chimeric IGH–MMSET gene by disrupting the MMSET gene within its first intron. MMSET plays a crucial role in chromatin remodeling as well as transformation in MM.

Several studies have confirmed that a poor prognosis is associated with the t(4;14); however, some of the newer therapies such as bortezomib are able to overcome the poor outcomes associated with t(4;14). It is interesting to note that genetic studies using FISH have identified the presence of del(13) in at least 85% of the patients with t(4;14). The reasons for this strong association are so far unknown. Both FGFR3 and MMSET are potential therapeutic targets, and several tyrosine kinase inhibitors are currently being tested to inhibit FGFR3 function.

The t(14;16)(q32;q23) involves the *c-maf* gene located at the 16q23 breakpoint. c-*maf* is a basic zipper transcription factor that positively regulates cyclin D2 and ITGB7. Although this translocation is reported in only 5% of MM patients, it is observed in 25% of MM cell lines, suggesting its role in cell proliferation as well as association with aggressive behavior of the disease. t(14;16) is considered to be associated with a poor prognosis. The other translocation partner of 14q32 is 20q11, observed in fewer than 5% of patients, and it dysregulates *MAFB* expression, another basic transcription factor belonging to the MAF family, with as yet unclear molecular consequences. It is also considered to be associated with a poor outcome; however, studies have been very small because of its infrequent occurrence.

Although c-myc is increasingly considered to play a role in myeloma pathobiology, t(8;14) translocations involving c-myc are rarely reported in myeloma, unlike Burkitt lymphoma, in which it is considered a classic feature. Almost 20% of patients with 14q32 translocation have other partners with unclear clinical or molecular significance.

Deletion 17p

Loss of the short arm of chromosome 17, (del(17p)) has been described in about 10% of patients with early stage MM. The deletion involves the major part of the short arm of chromosome 17 with consequent loss of number of genes. The most prominent gene in this region is TP53, which has been the focus of most investigations. However, p53 abnormalities represent an important late event associated with progression to an aggressive form of the disease. A study of

p53 gene mutations in 52 patients with myeloma showed that seven of 52 patients had p53 abnormalities, all with advanced clinically aggressive acute or leukemic stage of MM. Because p53 is involved in cell death induced by most therapeutic agents, its inactivation may lead to the chemoresistance and consequent poor prognosis observed in patients with del(17p). However, this hypothesis has yet to be confirmed. In contrast to translocations involving the 14q32 region, del(17p) is considered as a secondary event mostly acquired during evolution. Patients presenting with a del(17p) have a poor prognosis despite the use of novel agent combinations or HDT and transplant. Mutations of the *TP53* gene are a rare event in myeloma, especially at diagnosis.[3]

Deletion 13q14

Deletion of chromosome 13 or part of its long arm is detected in approximately 15% to 20% of the patients by conventional cytogenetics and by interphase FISH in 50% of the patients. Interestingly, del(13q) is also detected in 50% of patients with MGUS by FISH, predominantly in a small subpopulation of cells, indicating that it is a secondary genetic event occurring after initial clonal expansion. Although the retinoblastoma gene is present in the deleted region, the exact molecular consequence of del(13q) has not yet been ascertained. A number of studies, especially with conventional agents as well as HDT, have identified del(13q) to be a poor prognostic feature in myeloma; however, recent studies have identified that there is an association between del(13q) and t(4;14) and in the absence of t(4;14), del(13q) by itself is not associated with a poor prognosis, especially with the use of novel agents.[3] However, del(13q) detected by conventional cytogenetics is still considered a poor prognostic feature. Interestingly, del(13q) is also common in chronic lymphocytic leukemia but does not confer an adverse prognosis.

Abnormalities of the 1q Region

Recent studies have reported the biological role and prognostic implications of a gain of 1q. In fact, this is one of the frequently reported cytogenetic abnormalities in MM, being described in about one-third of the patients. This abnormality has also been reported in a number of other hematologic and solid tumors. A gain of 1q21 chromosomal region or overexpression of the *CKS1B* gene located in this region is associated with a poor outcome; however, further studies are required to ascertain the clear prognostic impact of 1q gains. A number of important genes in addition to CKS1B are located in this region, including the interleukin-6 (IL-6) receptor.[3]

GENOMICS

Expression Profiling

Several investigators have performed high-throughput expression profiling to better understand the pathobiology of myeloma, develop prognostic models, identify new targets for drug development and develop personalized medicine approaches. In these studies, RNA is extracted from purified $CD138^+$ myeloma cells and hybridized on high-density arrays to evaluate expression of genes from the whole transcribed genome. One of the first such analyses using unsupervised clustering identified sequential genetic changes from normal plasma cells to plasma cells from patients with MGUS and MM and provided clues to the molecular basis for malignant transformation and potential therapeutic targets.

Expression profiling in combination with cytogenetic changes has been used to classify myeloma into phenotypic and molecular subgroups as well as for prognosis. The molecular classification compared profiles from MM cells with those from MGUS representing an initial indolent form of the disease and MM cell lines representing cells with a more aggressive phenotype. A later, more detailed classification identified different subgroups, mainly based on cyclin D gene expression and on the different 14q32 translocations. This molecular classification refined in 2006 identified seven subclasses of myeloma. In this model, the first class was defined by the translocation t(4;14) and identified by overexpression of the *MMSET* or *FGFR3* genes (or both genes). The second class was related to the translocations t(14;16) or t(14;20) and was defined by upregulation of one of the *MAF* genes. Individuals with CCND1 or CCND3 upregulation (caused by the translocations t(11;14) or t(6;14)) clustered in two different groups named CD1 and CD2. The CD2 group was characterized by CD20 expression. The fifth group was characterized by hyperdiploidy. The last two groups were characterized by a low incidence of bone disease, according to low DKK1 expression, and the last group was characterized by increased expression of genes involved in proliferation. This molecular classification has been further modified by the Dutch-Belgian Hemato-Oncology Group (HOVON). This analysis did not confirm the "low bone disease" group, but three other subgroups were identified: one group characterized by overexpression of cancer testis antigen genes, another group defined by overexpression of positive regulators of the nuclear factor kappa-B (NFκB) pathway, and a third subgroup enriched for "myeloid" genes (unclear significance).[5]

Copy Number Alteration

DNA-based high-throughput techniques such as array comparative genomic hybridization (array-CGH) and high-density single nucleotide polymorphism (SNP) arrays have identified recurrent copy number alterations. These studies have identified significant molecular heterogeneity (Fig. 85-3).[6] Copy number alterations (CAN) have been observed in 98% of evaluated 192 newly diagnosed patients with MM. Two distinct groups were observed in these patients: One group of patients shows a hyperdiploid phenotype with gains of chromosomes 3, 5, 7, 9, 11, 15, 18, 19, and 21 or loss of chromosomes 13, 22, and X (in female cases). The second group is characterized by gain or loss of subchromosomal region. This includes deletion of 1p, 6q, 8p, 12p, 14q, 16p, 16q, and 20p, as well as amplification of 1q and 6p. The genomic heterogeneity observed within the hyperdiploid group is driven by the presence of gain of copies of chromosome 1q or chromosome 11, chromosome 13 loss, or chromosome 5 gain. Subclasses of hyperdiploid MM patients and their correlation with gene expression profiles provide a basis for identifying therapeutically targetable genes. The molecular basis of this genomic heterogeneity may stem from uncontrolled recombination activity, which may drive continued acquisition of genomic changes.

To identify genetic events underlying the genesis and progression of MM, a high-resolution analysis of recurrent copy number alterations using array comparative genomic hybridization (aCGH) and expression profiles were prepared from a collection of MM cell lines and outcome-annotated clinical specimens.[7] Attesting to the molecular heterogeneity of MM, distinct genomic subtypes along with 87 discrete minimal common regions (MCRs) within recurrent and highly focal CNAs were identified. The genes residing in these regions provide a genomic framework to understand the biology of MM as well as identify potential therapeutic targets.

Transcriptome Modifiers

Alternate splicing is an important posttranslational modification that allows production of multiple protein isoforms, and more than 90% of human genes undergo alternative splicing. The spliced isoform frequency varies between tissues, and these protein isoforms may have related, distinct, or even opposing functions. Changes in alternative splicing has been reported in myeloma cells compared with normal plasma cells, and these changes have been correlated with an effect on overall clinical outcome.

MicroRNAs are a class of small noncoding RNAs that cleave specific targeted transcripts, inhibiting translational of specific genes.

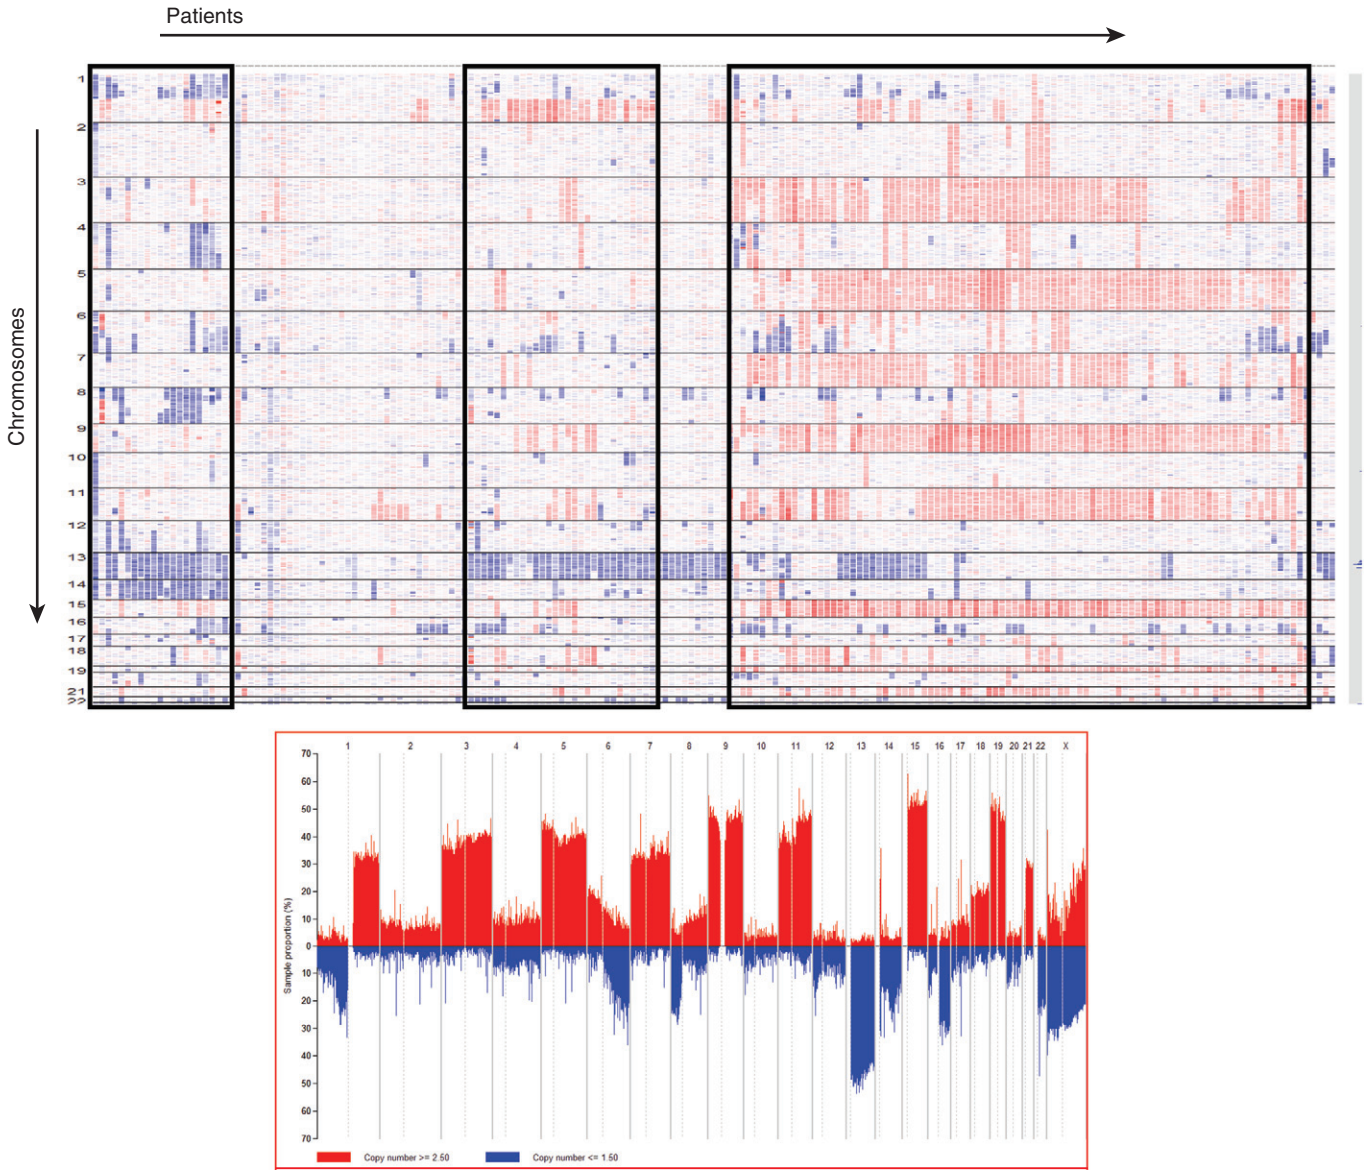

Figure 85-3 UNSUPERVISED HIERARCHICAL CLUSTERING OF SINGLE NUCLEOTIDE POLYMORPHISM (SNP) ARRAY–BASED DATA IN 192 PATIENT SAMPLES. Each column represents a patient and SNPs are arranged from 1p(tel) to Xq(tel) from top to bottom, so copy number changes are depicted from top to bottom for each chromosome. *Red* suggests gain, and *blue* suggests loss of copy number *(upper).* Recurrence of copy-number abnormalities (CNAs) across 192 MM patients in chromosomal order. *Red* or *blue bars* denote gain or loss of chromosome material *(lower).* The figure identifies recurrent areas of gains and losses in MM with identification of genomic subgroups and potential therapeutic targets. *(Adapted from Avet-Loiseau H, Li C, Magrangeas F, et al: Prognostic significance of copy-number alterations in multiple myeloma.* J Clin Oncol *27:4585, 2009.)*

Differences in expression patterns of microRNAs have been observed between MM and MGUS. For example, miRs -32, and -17-92 are overexpressed only in MM, but MiRs-21, -106b-25, and -181a/b show a similar expression pattern in both MM and MGUS but are highly expressed compared with normal plasma cells, providing a possible clue to events underlying progression from MGUS to MM. MiRs 15a/-16, are present on chromosome 13, and their downregulation is described in a subset of myeloma. Although this does not strictly correlate with chromosome 13 deletion, which is observed in almost half of MM patients, a potential effect of these MiRs on MM cell proliferation has been described. A similar attempt at correlating observed cytogenetic changes and their effects on MiR expression has identified overexpression of miR-let 7e, -125-5p, and -99b in patients with t(4;14) translocation and miRs -1 and -133a in patients with t(14;16) MM. A causal relationship between changes in these MiR expressions and their effects on target genes and eventual phenotypic changes in myeloma still needs to be established.[8] As in gene expression profiling, microRNA expression profile also identifies subgroups with different clinical outcomes, highlighting a significant role of microRNAs in MM biology and possibly as a therapeutic target. An integrated analysis of mRNA and miR profiling has now begun to identify regulatory networks that combine microRNA–mRNA pairs that may drive the eventually behavior of tumor cells. One such network combines p53/MDM2 expression with the downregulation of miRs -192, -194, and -215 in subset of MM. Such analysis will help explain some of the genomic changes observed in myelomagenesis and its progression.

A genome-wide methylation profile has identified hypomethylation, a characteristic that differentiates nonmalignant from malignant plasma cells.[9] Different methylation patterns have been observed between MGUS and MM cells, explaining their effect of gene expression patterns and the behavior of myeloma cells. Similarly, differential or downregulated expression of genes involved in cell–cell signaling and cell adhesion in plasma cell leukemia cells can be explained by

the observed remethylation of these genes in leukemic cells. The downregulated adhesion genes can then explain the development of independence from their interaction with BM stromal cells and release in the circulation. Epigenetic changes modulating myeloma cell growth and survival genes have also been reported. For example, methylation of p16, a negative cell cycle regulator, is reported as an early event in MGUS. However, p16 methylation has not been shown to be predictive of OS in a larger cohort study.

Sequencing

Gene sequencing studies in myeloma have to date failed to identify a predominant mutation driving the disease process. A whole-genome or -exome sequencing study of 39 patients (22 whole genomes and 17 whole exomes) using 30X coverage has identified a number of recurrent unique but low-frequency mutations involving histone methyltransferases, transcription factor IRF4, BRAF, genes involved in protein translation, and genes involved in blood coagulation.[10] A separate study using massively parallel whole-genome paired end sequencing on paired samples collected 6 months apart in two myeloma patients identified 29 somatic rearrangements, including three that were present only in the second sample, suggesting both the presence of genomic changes early on as well as acquisition of new changes over time. These initial sequencing efforts confirm the potential of whole-genome sequencing to provide a true insight into the molecular pathogenesis in myeloma that may affect therapy in the future.

MICROENVIRONMENT

Bone Marrow Stromal Cells and Signaling

Myeloma cells interact with BM stromal cells, leading to both local cytokine production and both cytokine-mediated and adhesion-mediated signaling changes. The MM–BM stromal cell (BMSC) adhesion is mediated by the adhesion molecules expressed on myeloma cells (Table 85-2) and their interacting partners on the BMSCs as well as the extracellular matrix proteins. Adhesion and associated signaling changes affect the migration and localization of the myeloma cells in the BM. Moreover, proliferative and antiapoptotic signaling cascades activated in myeloma as a result of these interactions include phosphatidylinositol-3 kinase (PI3K)/Akt, Ras/Raf/mitogen-activated protein kinase (MAPK) kinase (MEKK)/extracellular signal-related kinase (ERK), Janus kinase (JAK) 2/signal transducers and activators of transcription 3 (STAT 3), and NFκB pathways. These pathways lead to MM cell growth, survival, antiapoptosis, and development of drug resistance (Fig. 85-4).[11]

For example, syndecan-1, a cell surface transmembrane heparan sulfate proteoglycan present on MM cells, interacts with type I collagen and regulates the growth of MM cells; it also mediates increased osteoclast activity. Elevated levels of syndecan-1 shed into serum correlate with increased tumor mass, decreased matrix metalloproteinase-9 activity in serum, and a poor prognosis.

Various cellular components constitute the BM milieu, including osteoclasts, osteoblasts, endothelial cells, and immune cells, each contributing differently and distinctly to the overall effect of the microenvironment. For example, the cross-talk between tumor cells and components of the BM composed of osteoclasts and osteoblasts helps propagate not only the development of osteolytic lesions but also consequent survival and proliferation of MM cells. Several cytokines and signaling pathways have been identified as important mediators in the disruption of the osteoclast–osteoblast axis.[12] Impaired osteoblastogenesis is caused by the release of WNT inhibitors such as DKK1 have been studied, and neutralizing DKK1 antibody suppresses tumor-induced bone resorption and MM growth in vivo. Restoring normal bone homeostasis by disrupting this cross-talk thus represents a potential strategy to create a hostile niche for tumor growth. Similarly, endothelial cell proliferation and increased angiogenesis play an important role in plasma cell disorders. Compared with normal BM, increased BM microvessel density (MVD) has been observed in MGUS and MM. There is a stage-related increase in BM MVD that is also correlated with prognosis. Both vascular endothelial cell growth factor (VEGF) and hepatocyte growth factor (HGF) have been reported to be angiogenic factors expressed in myeloma. These results also suggest angiogenesis as a potential therapeutic target in myeloma and explains in part the efficacy of thalidomide and lenalidomide.

Activation of NFκB has been observed in myeloma cells, especially following their interaction with BMSCs. A number of abnormalities contributing to the dysregulation of NFκB and constitutive activation of the noncanonical NFκB pathway have been described,[11] In two separate studies, it has been shown that the NFκB pathway can be activated, either by deletions of NFκB inhibitors (e.g., TRAF3 or CYLD) or by activation of NFκB activators (e.g., NIK or CD40). Inactivating mutations of TRAF3 and elevated expression of NIK by genomic alterations or protein stabilization have been described and may explain the mechanism whereby MM cells achieve autonomy from the BM microenvironment.

*CD45 on immature myeloma cells.

Cytokines

Myeloma cell growth, survival, antiapoptosis, and drug resistance are in part mediated by a number of cytokines produced by MM cells as well as BMSCs. In fact, the production of cytokines is significantly modulated by MM–BMSC interactions and includes IL-6, insulin-like growth factor-1 (IGF-1), VEGF, tumor necrosis factor-α (TNF-α), transforming growth factor-β (TGFβ), IL-17, IL-21, CXC-chemokine ligand 12 (CXCL12), and others.[11]

Interleukin-6

Interleukin-6 is one of the most important cytokines, mediating both growth and survival of MM cells. IL-6 plays an important role in the

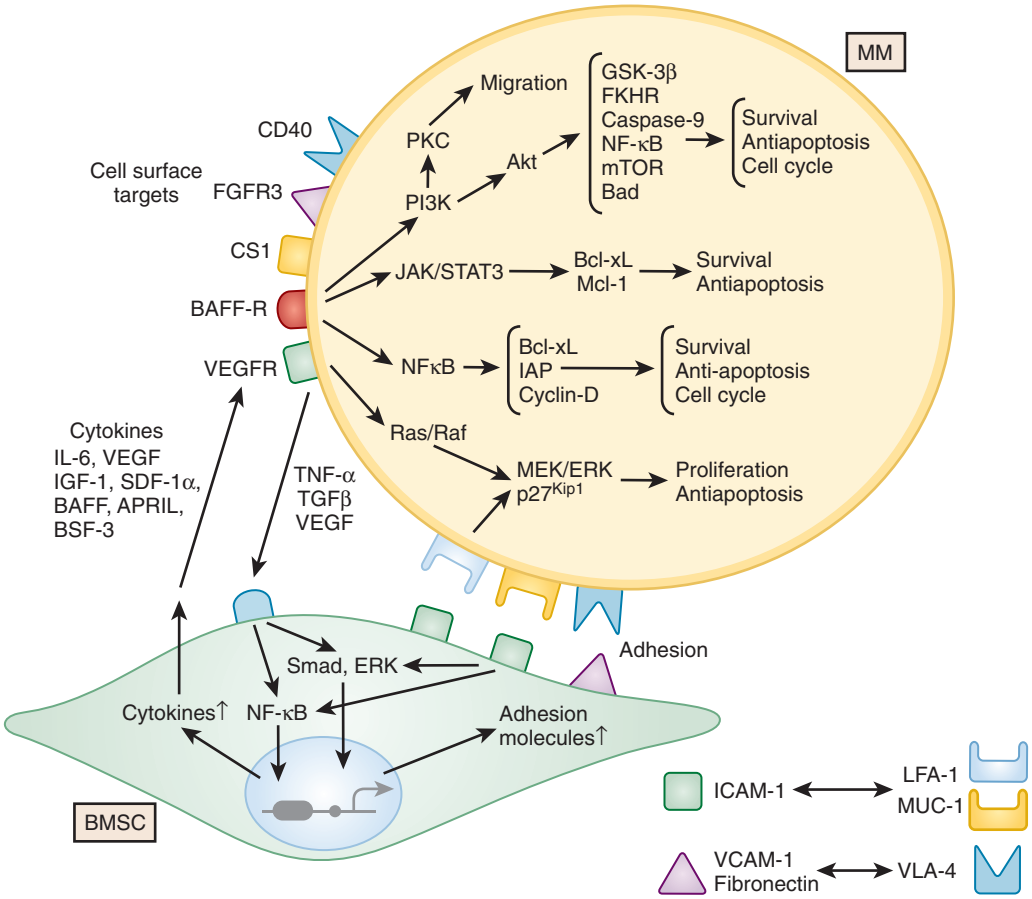

Figure 85-4 GROWTH OF THE MULTIPLE MYELOMA (MM) CELL IN THE BONE MARROW (BM) MICROENVIRONMENT. The interaction and adhesion of MM cells to the BM stromal cells (BMSCs) lead to adhesion- and cytokine-mediated signaling. MM cells binding to BMSCs induce the activation of p42/44 mitogen-activated protein kinase (MAPK) and nuclear factor kappa-B (NFκB) in BMSCs. The activation of NFκB upregulates adhesion molecules on BMSCs. Cytokines secreted through this interaction include interleukin-6 (IL-6) secretion, tumor-necrosis factor-α (TNF-α), and vascular endothelial growth factor (VEGF) to activate the main signaling pathways (p42/44 mitogen-activated protein kinase [MAPK], Janus kinase [JAK]/signal transducer and activator of transcription 3 [STAT3], or phosphatidylinositol 3-kinase [PI3K]/AKT) and their downstream targets, which triggers MM cell growth, survival, and migration. The RAS/RAF/MAPK kinase (MEK)/MAPK pathway mediates proliferation of MM cells. JAK/STAT3 along with upregulation of BCL-X_L and MCL1 mediates survival. PI3K/AKT through downstream activation of BAD and NFκB or inactivation of caspase-9 mediates antiapoptosis. NFκB and forkhead in rhabdomyosarcoma (FKHR) modulate cyclin D and KIP1, thereby regulating cell cycle progression. Signaling through PI3K induces downstream protein kinase C (PKC) activity and MM cell migration. *APRIL,* A proliferation-inducing ligand; *BAFF,* B-cell activating factor; *BSF-3,* B-cell stimulating factor; *ERK,* extracellular signal-related kinase; *FGFR3,* fibroblast growth factor receptor 3; *ICAM1,* intercellular adhesion molecule 1; *IGF1,* insulinlike growth factor-1; *IL,* interleukin; *LFA1,* lymphocyte function–associated antigen 1; *MEK,* MAPK/ERK kinase; *mTOR,* mammalian target of rapamycin; *muc1,* mucin 1; *SDF-1α,* stromal cell–derived factor-1α; *VCAM1,* vascular cell adhesion molecule 1; *VLA4,* very-late antigen 4. *(Adapted from Hideshima T, Mitsiades C, Tonon G, et al: Understanding MM pathogenesis in the bone marrow to identify new therapeutic targets.* Nat Rev Cancer *7:585, 2007.)*

terminal differentiation and the proliferation of normal plasmablasts. The IL-6 receptor that is composed of an α chain (gp80) and a signal-transducing β chain (gp130) is expressed by myeloma cells. IL-6 binding to its receptor activates Ras/RAF/MEK/ERK, JAK/STAT, and PI3K/AKT signaling pathways, mediating growth, survival, and drug resistance, respectively. The major source of IL-6 production is the BM stroma with myeloma cells contributing to a smaller extent. IL-6 production is induced by MM-BMSC interactions as well as by other cytokines, including TNF-α and VEGF in the BM milieu. IL-6 mediates mainly in a paracrine fashion but also has, to some extent, autocrine activity. IL-6 has a number of other activities, including being responsible for the number of symptoms observed in patients, inducing anemia and thrombocytosis, inducing T regulatory as well as Th17 cells with associated immunosuppression, and mediating enhanced bone resorption by osteoclasts. Additionally, IL-6 promotes coagulation without affecting fibrinolysis and induces a prothrombotic state by increasing expression of fibrinogen, factor VIII, and von Willebrand factor and by increasing production of platelets as well as activation of endothelial cells, overall inducing a prothrombogenic state. Importantly, it confers resistance to antitumor agents, especially dexamethasone. Myeloma cells shed IL-6Rα and soluble IL-6R, which can transduce the response of myeloma cells to IL-6. High serum levels of IL-6 as well as IL-6R are considered to predict poor prognosis. Both IL-6 and IL-6R are thus therapeutic targets, and antibodies targeting them are in advanced stages of clinical development.

Insulinlike Growth Factor-1

Insulinlike growth factor-1, similar to IL-6, is a mitogenic factor secreted by myeloma cells and mediates growth and survival of

myeloma cells through activation of PI-3K and MAPK signaling pathways. IGF-1 receptor is expressed by myeloma cells, and binding of IGF-1 to its receptor activates both signaling pathways. IGF-1 also mediates adhesion and migration of myeloma cells via β1-integrin and upregulates FLIP, X-linked inhibitor of apoptosis (XIAP), and A1/Bfl1, thereby further enhancing tumor cell growth and survival. A number of IGF-binding proteins have been described that modulate IGF-1 activity. These molecular and signaling changes collectively lead to induction of drug resistance, especially to dexamethasone, which is greater than that observed with IL-6. These results have provided evidence for IGF-1 as an important therapeutic target.

Vascular Endothelial Growth Factor

Vascular endothelial growth factor is produced predominantly by myeloma cells, and its expression is enhanced by MM–BMSC interaction as well as by IL-6 and CD40 activation. It has only modest proliferative effects on myeloma cells but is the major factor affecting myeloma cell migration as well as angiogenesis. VEGF mediates part of its activity via Flt-1 phosphorylation and downstream activation of MEK and protein kinase C-α (PKC-α) signaling. Although these data suggest VEGF as a potential target, specific anti-VEGF therapeutics have not yet yielded significant clinical responses in myeloma.

Transforming Growth Factor-β

Transforming growth factor-β does not have direct effect on myeloma cells but has a number of activities that indirectly affect the clinical presentation of patients with myeloma. It is produced by MM cells and induces secretion of IL-6 by BMSCs. Importantly, it induces immunosuppression characteristic of myeloma and may also affect normal plasma cell development and function, thereby contributing to suppressed uninvolved immunoglobulin production in myeloma. It is also a major cytokine that affects T-helper cell development, especially T regulatory cells and Th17 cells.

Interleukin-17 and Proinflammatory Cytokines

Elevated levels of Th17 cells along with increased levels of serum IL-17 and associated proinflammatory cytokines, IL-21, IL-22, and IL-23, are observed in patients with myeloma. IL-17 has multiple effects in myeloma, including induction of myeloma cell growth; suppression of immune function, especially in association with IL-22; and induction of bone disease by inducing osteoclast number and function. IL-17 also induces IL-6 production by BMSCs, thereby augmenting its myeloma growth–inducing effects. IL-17 triggers phosphorylation of JAK1, STAT3, and ERK1/2. TNF-α upregulates expression of both IL-21 and of IL-21 receptor (IL-21R), and IL-21 induces proliferation and inhibits apoptosis of myeloma cells independent of IL-6 signaling.

Tumor Necrosis Factor-α

Tumor necrosis factor-α is primarily a mediator of inflammation. It is produced by myeloma cells and has no significant direct effect on myeloma cells. However, it mediates part of its activity through induction of IL-6 production by BMSCs. It induces activation of NFκB and adhesion molecules with a resultant increase in binding of myeloma cells to BMSC and mediates cell adhesion–mediated drug resistance. Antibodies specifically targeting TNF-α have not shown clinical activity. However, novel agents such as bortezomib and the immunomodulatory agents thalidomide and lenalidomide have potent anti–TNF-α activity and can overcome drug-resistance by eliminating TNF-α–induced NFκB activation.

Other Cytokines and Chemokines

CXCL-12 (SDF-1) is expressed by BMSCs, and its receptor CXCR4 is expressed by myeloma cells. It induces only a minimal proliferative effect; however, it plays a more important role in mediating migration.

Myeloma cells have been reported to express both IL-15 and IL-15 receptor with a possibility of an autocrine circuit.

Interleukin-10 is a cytokine produced primarily by monocytes and has pleiotropic effects on immunoregulation and inflammation. It has immunosuppressive activity with downregulation of the expression of Th1 cytokines. It is reported to stimulate proliferation of myeloma cells, and this activity can be abrogated by antibodies to the gpl30 transducer.

Hepatocyte growth factor (HGF), through its receptor c-met expressed on the majority of myeloma cells, promotes cell invasion, migration, and proliferation. It also induces differentiation and proliferation of osteoclasts and increases bone resorption in myeloma patients.

Immune Environment

Significant immune dysfunction is observed in myeloma involving both T cells and B-cell function as well as abnormalities in dendritic cell (DC), natural killer (NK) cell, and NKT-cell activity.[13-15] Significant phenotypic and functional aberrations in both $CD4^+$ and $CD8^+$ T cells have been observed in patients with both MGUS and MM. In MM, impaired action of viral-specific $CD8^+$ cells, particularly against influenza and Epstein-Barr virus (EBV), has been reported. Hyperactive T cells associated with impaired T-cell receptor (TCR) signaling and increased sensitivity to costimulatory signals have been reported in MM. In fact, further abnormalities of the TCR variable β-chain (TCR-Vβ) repertoire have been observed after chemotherapy in MM patients. A reduction in $CD4^+$ T-cell numbers and $CD4^+$:$CD8^+$ T-cell ratio is observed in the peripheral blood of MM patients. Persistent proliferative activity of both $CD4^+$ and $CD8^+$ T cells has been observed in both MGUS and MM, which plays a possible role in controlling tumor cell growth and survival. Overall hyperactivity, clonal expansion, and homeostatic proliferation of T-cell activity are observed. Moreover, $CD4^+$ and $CD8^+$ T cells from the BM of patients with MGUS are able to mount a strong immune response against autologous MGUS plasma cells; however, similar responses are not observed with T cells from the BM of MM patients, suggesting the role of the immune system in controlling plasma cell growth in MGUS and loss of immune surveillance in MM. Although in MM, T cells are dysfunctional in the BM, these cells can be stimulated in vitro leading to restored function. Regulatory T cells (Tregs): The $CD4^+/CD25^+$ T-helper cells specifically express forkhead box protein (Foxp) 3 and actively suppress inappropriate immune responses maintaining immune homeostasis. In MM, Tregs are lower in number and are dysfunctional. This may be mediated by elevated IL-6, sIL-6R and TGFβ levels. Another report suggests that after short exposure to IL-2, purified Tregs from MM patients are able to induce suppressive activity in vivo and in vitro. Therapy such as lenalidomide, granulocyte colony-stimulating factor (G-CSF), and allogeneic stem cell transplantation (SCT) may directly or indirectly affect Treg and may account for some of the observed variations in Treg number and function in MM. T-helper 17 (Th17) specifically express retinoic acid–related orphan receptor-γt (ROR-γt) and produce IL-17, which provides protection against certain bacterial, fungal, and viral infections. Development of Th17 cells is also determined by TGFβ and IL-6, which are upregulated in MM. In myeloma, an increased number of Th17 cells are reported with an associated increase in serum levels of IL-17 and other proinflammatory cytokines such as IL-21, IL-22, and IL-23. IL-17 has been reported to support myeloma cell growth, suppress immune function, and induce osteoclastogenesis, supporting bone disease in MM. These effects make Th17 cells an important therapeutic target in MM. γδ T cells possess a distinct TCR and represent a small subset of T cells involved in generating

an antimyeloma response. γδ T cells are considered a bridge between innate and adaptive immunity and are able to kill major histocompatibility (MHC) class I chain-related protein A (MICA)–positive MM cells via the NKG2D (a NK-cell triggering receptor) pathway. Interestingly, MICA expression is significantly higher in plasma cells from MGUS patients. Bisphosphonates have been shown to activate γδ T cells, which may in part explain their weak antimyeloma activity.

Significant B-cell and plasma cell dysfunction is observed in MM as represented by suppressed uninvolved immunoglobulins. For example, in patients with IgA myeloma, there is suppression of serum IgG and IgM levels. This is not considered to be mediated by high levels of monoclonal paraprotein because suppressed immunoglobulins have also been observed in patients with nonsecretory disease. An explanation for this observation remains elusive; however, suppressed uninvolved immunoglobulins predispose patients to infectious complications because they reduce the patient's ability to generate a specific humoral immune response to infections or vaccinations. For example, a study evaluating the serologic responses to vaccinations against influenza, streptococcus pneumoniae, and *Haemophilus influenzae* in 52 MM patients reported that only 19% developed protective antibody titer levels against influenza, 39% against streptococcus pneumoniae, and 41% against *H. influenzae* type b. These observations suggest the necessity to define suitable immunization protocols for patients with MM and the need to study the humoral and cellular responses after vaccination in terms of clinical efficacy, magnitude, and duration of response. Both B- and T-cell immune function is also affected by the therapeutic agents themselves with further increase in the risk of infectious complications (e.g., the increased risk of herpes zoster after bortezomib treatment or bacterial infections after dexamethasone use in MM). Recovery of uninvolved immunoglobulins to normal levels after effective therapy has been associated with both improved survival and protection from infectious complications.

Alterations in NK cell number have been observed in MM and are correlated with disease burden (e.g., high numbers of NK cells have been observed in patients with a low tumor burden). NK cells are considered to have a potential therapeutic role, and the immunomodulatory drugs (thalidomide, lenalidomide, and pomalidomide) enhance NK cell–mediated cytotoxicity against MM cells. Invariant natural killer T cells (iNKTs), which constitute an innate lymphocyte lineage with potential for a potent antitumor immune response through the production of Th1 cytokines, are functionally defective in MM; however, these cells can be cultured in vitro with restored function, suggesting the possibility of their adoptive transfer as a potential therapeutic strategy in MM.

Dendritic cells are important antigen-presenting cells (APCs) that generate effective immune responses, including antitumor responses. DC dysfunction partly mediated by cytokines such as VEGF, IL-10, and TGFβ is reported in MM. However, it is possible to improve the defective DC function by in vitro generation. A number of studies have used DC-based vaccination strategies, including vaccinations with DCs pulsed with the idiotype protein. DCs pulsed with MM antigen-directed peptides or MM cell lysate and fusion of MM cells with DCs have been reported to lead to an antimyeloma immune response after vaccination.

CLINICAL MANIFESTATIONS

Patients with MM present with a number of signs and symptoms that are either related to BM infiltration by plasma cells or caused by manifestations of end-organ damage involving renal dysfunction, bone lesions, or immunoparesis. However, in up to 20% of the patients, MM may present entirely as an asymptomatic disease diagnosed on routine blood work. The symptoms may also be related to deposition of paraproteins in various organs as either light-chain deposition or amyloid deposits or caused by cytokines such as IL-6 or VEGF produced by the myeloma cells or the BM stromal cells. Because of improvement in routine blood work and the availability of sensitive tests, the clinical presentation in myeloma has changed over the past 25 years (Table 85-3). Overall, patients are more frequently being diagnosed with asymptomatic disease than presenting with symptoms. For example, patients are presenting less often with bone pain, pathological fractures, and renal failure as well as hyperviscosity. Various clinical features of myeloma are summarized in Table 85-4.

Bone Disease

Almost two-thirds of patients with MM present with bone pain as their main symptom. The mechanism of bone involvement is

Table 85-3 Changing Clinical Presentation of Patients With Myeloma

Epistaxis

multifactorial, including direct bone destruction by the unbalanced hyperactivity of osteoclasts and suppression of osteoblastic activity. This is further accentuated by the cytokine milieu generated in the BM microenvironment by interaction between myeloma cells and BMSCs; this includes IL-6, IL-1β, TNF-α, and MIP1α.[12] A member of the TNF family, RANKL (receptor activator of nuclear factor κ-B ligand), also plays an important role in osteoclast growth and differentiation via its receptor located on osteoclasts. RANKL is secreted by stromal cells and osteoblasts, and induces differentiation and maturation of osteoclast progenitors. Osteoprotegerin (OPG) acts as a decoy receptor for RANKL and plays a significant role in development of bone disease in myeloma. In myeloma, the soluble syndecan produced by myeloma cells occupies and sequesters OPG, leading to excess RANKL activity that induces osteoclast differentiation and proliferation with the development of consequent lytic bone lesions. Importantly, myeloma cells also secrete Dick Kopf–related protein 1 (DKK-1), which has significant osteoblast inhibitory activity, leading to suppression of new bone formation, further contributing to bone disease in myeloma.[16] Thus DKK-1 has become an important therapeutic target to improve bone anabolic effects in myeloma. These factors together lead to osteoporosis and lytic bone lesions. Additionally, direct infiltration of bone by myeloma cells also causes bone destruction. Overall, one observes pain that is aggravated on movement and also collapse of vertebrae, leading to a decrease in height as well as symptoms of nerve compression. Besides pain, involvement of the extremities or spine leads to lack of mobility and associated problems, including predisposition to thrombotic events.

Hypercalcemia

Hypercalcemia is observed in approximately 25% to 30% of patients with myeloma and is usually a manifestation of higher burden of the disease. Its occurrence is related to bone involvement as well as production of various cytokines that lead to increased bone resorption and calcium release. Hypercalcemia manifests as mental status changes, lethargy, nausea and vomiting, and constipation. In extreme cases, one can also develop seizure activity. A normal serum calcium level in the presence of high paraprotein or low albumen level may require calculation or measurement of ionized calcium levels to assess true and effective serum calcium levels. Hypercalcemia can also induce renal failure caused by dehydration and it is to be considered a hematologic emergency, meriting prompt intervention.

Renal Failure

Renal insufficiency is one of the frequent and serious complications of myeloma with a multifactorial etiology.[17] The most common and reversible cause of renal failure is light-chain tubular cast deposition or light-chain deposition disease (commonly associated with κ light chains). Similarly, proteins can be deposited as amyloid, predominantly involving λ light chain (specifically λ light-chain subtype 6) with development of kidney failure. Amyloidosis is quite often associated with nephrotic (syndrome) range proteinuria. The proteinuria observed in patients with amyloid is more nonspecific, which differs from conditions with light-chain cast nephropathy with predominantly excess of light-chain excretion in the urine. Another common cause is hypercalcemia leading to osmotic diuresis and prerenal dysfunction associated with volume depletion. Additional mechanisms of renal failure in myeloma include renal calcium deposition with interstitial nephritis, use of nonsteroidal antiinflammatory drugs for pain control, hyperuricemia, intravenous contrast dye use for imaging purposes, chemotherapy-induced nephrotoxicity, and use of bisphosphonates. The development of light-chain cast nephropathy has been reported to be associated with Tom-Horsfall protein, which promotes heterotypic aggregation of light chains with deposition in the distal tubules of the kidney. Patients with renal failure are often asymptomatic. However, when symptoms are present, they are predominately malaise, weakness, nausea, or vomiting.

Anemia

Anemia is one of the common presenting symptoms in myeloma and is symptomatically associated with fatigue and shortness of breath. Anemia usually is normochromic normocytic and has a number of etiologic factors associated, including inadequate erythropoietin production caused by renal dysfunction, erythropoietin unresponsiveness predominately caused by various cytokines produced in myeloma, dilution caused by significantly increased immunoglobulin levels, and BM infiltrative processes.[18] Part of the development of anemia may also be related to high IL-6 levels. In patients who have had a number of treatments, quite often anemia is related to repeated rounds of chemotherapy. Erythropoietin administration therefore is an important supportive measure for the symptomatic treatment of anemia in myeloma. In one study, improvement in hemoglobin was observed in 60% of treated patients, and responses were observed in those with low erythropoietin levels compared with normal or high level (72% vs. 20%).

Neurologic Symptoms

Patients with MM present with a number of neurologic symptoms related either to direct involvement of the nervous system or the impact of cytokine or paraproteins on the nervous system. The most common abnormality is compression of the spinal cord or nerve roots, giving rise to pain as well as various degrees of neurologic dysfunction, including, in several cases, paraplegia with loss of bladder and bowel control. Cord compression is considered a neurologic emergency requiring prompt intervention, which in fact might allow complete recovery of function as well as resolution of a majority of the symptoms. In this setting, an urgent magnetic resonance imaging (MRI) followed by radiotherapeutic or surgical intervention is immediately warranted. Peripheral neuropathy is another common manifestation observed in almost one-third of the newly diagnosed patients, if analyzed using sophisticated and sensitive methods. Peripheral neuropathy also can develop because of a therapeutic intervention, especially agents such as thalidomide, bortezomib, and vincristine. Moreover, a constellation of symptoms associated with POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes) includes prominent sensory neuropathy associated with sclerotic myeloma. Paraneoplastic central nervous system (CNS) manifestations have been occasionally reported in myeloma and are considered to be related to clonal immunoglobulin targeting various CNS cells or structure. Furthermore, the polyneuropathy in myeloma is caused by multiple other factors, including amyloid deposits, infiltrative processes with other protein deposits, metabolic causes related to hypercalcemia or hyperviscosity, immune processes, or cytokine effects. IgM-related neuropathy is well described in which case a myelin-associated globulin (MAG) has been described in 50% of the patients. The presence of MAG provides diagnostic clues as well as a parameter to follow therapy. Traditionally, meningeal involvement has been described very rarely in myeloma; however, with prolonged survival with novel agents, it is being seen more frequently. This type of complication is usually observed with high-risk disease. Finally, intracranial plasmacytomas involving brain parenchyma, either from the skull or from the skull base, has been reported in advanced cases.

Hyperviscosity

Hyperviscosity is less frequent in myeloma compared with Waldenström macroglobulinemia, in which higher molecular weight IgM molecules frequently cause an increase in viscosity. In general, hyperviscosity in IgG myeloma is extremely uncommon. For hyperviscosity to develop, generally an IgG greater than 10 g/dL, IgA greater than 7 g/dL, and IgM greater than 5 g/dL is required to cause symptomatology. Occasionally, certain physicochemical characteristics of immunoglobulin may lead to self-aggregating properties and induce viscosity even at a lower level. This has been reported with IgG3,

which is more frequently associated with hyperviscosity among various IgG myelomas. The commonly observed symptoms are related to circulatory decline involving vital organs, leading to complaints of headache, visual symptoms, shortness of breath, bleeding complications such as nosebleeds, and eventually mental status changes. The confirmation of viscosity can be obtained by measuring viscosity, which may exceed 4.0 cp units; however, symptoms at lower levels of viscosity have been observed. Therapy is instituted more on the basis of symptomatology than absolute measured levels of viscosity and requires prompt institution of plasmapheresis with quick resolution of symptoms.

Infections

Infections are some of the most important causes of morbidity and a common cause of mortality in myeloma. Because of compromised T- and B-cell functions, myeloma patients are at a significant high risk of developing recurrent bacterial as well as viral and fungal infections. As described earlier, various factors lead to an inability of myeloma patients to mount a humoral immune response to antigens or an infectious challenge.[19] The patients are susceptible to polysaccharide-encapsulated organisms as well as enteric gram-negative bacilli. Further susceptibility to infections also stems from therapeutic intervention, especially with corticosteroids. For example, fungal infections, most commonly, oral thrush, are observed after high-dose dexamethasone-based therapy, and herpes zoster is observed frequently after bortezomib-based therapy. In both cases, prophylactic antibiotics or antivirals are indicated. A number of cases of therapy-induced activation of mycobacterium tuberculosis in developing countries have been reported. The risk of infection is highest during the first 2 months of initiation of therapy when both myeloma-related immunosuppression as well as therapy-related immunosuppression increase the predisposition to infectious complication. Prompt diagnosis of infectious complications and quick institution of therapy or preferably initial prophylactic measures prevent major complications.

Coagulation Disorders

Both BM suppression with cytopenias and coagulation abnormalities are observed in myeloma. Myeloma might be associated with both bleeding-related problems as well as thrombotic events. The coagulation abnormalities are related to high levels of paraprotein that interfere with normal coagulation pathways as well as platelet dysfunction caused by either decreased number or function. The coagulation abnormalities include conditions similar to acquired deficiency of factor VIII. The hypercoagulable state is observed in 15% of patients with IgG myeloma and one-third of patients with IgA myeloma and is related to hyperviscosity, acquired activated protein C resistance, lupus-like anticoagulants with thromboembolic complications, acquired deficiency of protein S, and a therapy-related hypercoagulable state specifically with immunomodulatory agents such as thalidomide and lenalidomide. In the absence of prophylactics measure, these agents have been reported to cause deep venous thrombosis (DVT) in 10% to 20% of these patients, in whom the thrombotic risk increases with associated use of dexamethasone, other chemotherapeutic agents, or a previous history of DVT or immobility.

Thrombocytosis is more frequently associated with myeloma than thrombocytopenia, mainly driven by the high level of IL-6, which drives growth and maturation of megakaryocytes. Rarely, extensive BM infiltration by myeloma cells, and more commonly, extensive chemotherapeutic intervention with BM compromise leads to thrombocytopenia in the advanced stages of the disease.

Amyloidosis

The monoclonal protein, specifically the light chain, can get deposited in various organs as an insoluble fibrillar protein, amyloid, affecting organ dysfunction. Around 20% of patients with primary amyloidosis (AL) also have a concurrent diagnosis of MM, and all patients with AL-amyloid have clonal light chain production. Although clinically overt amyloidosis is observed less frequently in myeloma, intense investigation to identify amyloid deposits using fat pad biopsies, concurrent staining of BM with Sudan black, and obtaining rectal biopsy can identify some level of amyloid deposit in almost one-third of the patients. Patients with amyloid deposits can present with a number of features primarily related to their organ damage, including renal and cardiac dysfunction and symptoms suggesting carpal tunnel syndrome. Classic presentations of advance amyloid include cutaneous fragility around the eyelids with raccoon eyes and macroglossia. Patients with advanced amyloid with myeloma have a poor overall outcome; however, therapeutic intervention currently remains the same as in patients with myeloma with amyloidosis.

LABORATORY MANIFESTATIONS

Investigations to Detect Clonality

Protein Electrophoresis

A serum protein electrophoresis is performed to quantitate the monoclonal proteins present in myeloma.[20] In 70% of the patients, the monoclonal protein is IgG; in 20%, it is IgA; and in 5% to 10% of patients, it is light chains only. Fewer than 1% of patients have monoclonal protein, which is IgD, IgE, or IgM, or truly nonsecretory myeloma. The identification of the exact type of paraproteins in both serum and urine requires immunofixation (Fig. 85-5). This should be performed at the time of initial diagnosis and needs to be repeated to confirm achievement of complete response. Patients who produce intact immunoglobulins can also produce excess light chain, leading to a diagnosis that has both heavy and light chains (e.g., patients can have IgG κ and κ light-chain myeloma). Associated with the presence of a monoclonal protein, the uninvolved immunoglobulins are suppressed in MM. For example, patients with IgG myeloma have suppressed IgA and IgM. In a setting where all three immunoglobulins are suppressed, one should suspect either light chain–only disease or the possibility of IgD or IgE MM. Very rarely, a biclonal or triclonal pattern of immunoglobulins is observed, more often with the same light chain but rarely with different heterotypic light chains. This may suggest truly separate clones, especially with separate light chains. Quantitation of Bence Jones proteins in urine is still important both for the diagnosis of myeloma as well as for follow-up. It is important to note that free light-chain measurement in urine is not informative. Those patients with only monoclonal protein in the urine require frequent 24-hour Bence Jones proteins measurements for follow-up. Therapeutically, patients with all the various types of immunoglobulins are treated with a similar approach; however, a patient with IgA myeloma appears to have an inferior survival. The immunoglobulin isotype remains constant in a given patient over the natural history of the disease; however, occasionally, a patient producing one immunoglobulin at the time of diagnosis, at relapse, or with advanced disease may present with only the same light chain as initially observed with the original immunoglobulin (light-chain escape) or occasionally may become nonsecretory. Both the changes are reflective of the change in plasma cells to a more aggressive or undifferentiated form. Because of the observed light-chain escape, patients without initial Bence Jones proteins detection in urine will require periodic 24-hour urine Bence Jones proteins measurements on follow-up.

The unique sequences that are observed with the idiotype protein (CDR3) have been used as a marker that specifically identifies tumor cell clone and has been applied to polymerase chain reaction–based methodology to detect minimal residual disease (MRD) with high sensitivity. Early studies using such molecular methods for detecting MRD have identified patients who achieve molecular CRs that are associated with improved overall outcome.

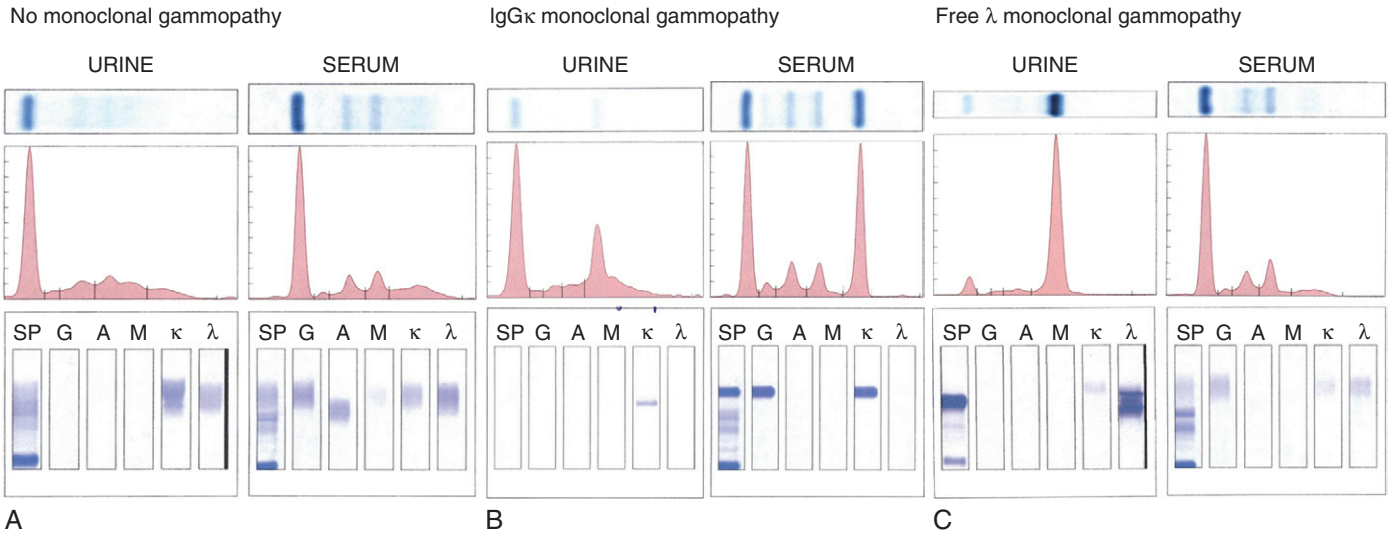

Figure 85-5 REPRESENTATIVE PATTERNS OF SERUM ELECTROPHORESIS AND IMMUNOFIXATION. In each figure, the *lower panels* represent immunofixation patterns, *middle panels* are the densitometric tracing of the gel, and *upper panels* are agarose gel of urine sample *(left)* and serum *(right).* **A,** The normal pattern of serum and urine protein on electrophoresis. Because there are many different immunoglobulins in the serum, their differing mobilities in an electric field produce a broad peak. **B,** In monoclonal gammopathies, the predominance of a product of a single cell produces a sharp peak. The immunofixation identifies the type of immunoglobulin (e.g., κ light chain in urine and IgG κ in serum). **C,** In patients with light chain–only disease, a clonal band is observed only in urine with no clear peak in serum (e.g., γ light chain in urine with no distinct immunofixation positivity in serum). *(Courtesy Dr. Neal I Lindeman, with permission.)*

Serum-Free Light Chain

This test measures light chain that is not associated with heavy chain that forms the intact immunoglobulin molecule. The presence of serum-free light chains provides an additional marker and measurement of plasma cell proliferation, and its quantitation has allowed us to determine protein levels in a number of patients who were previously considered oligo or nonsecretory. For example, 80% of patients with previously diagnosed nonsecretory myeloma have measurable serum-free light chains. Routine use of serum-free light chain measurements is indicated for diagnosis, response evaluation, and prognosis. As shown later, in patients with MGUS and SMM, the serum-free light-chain ratio allows for identification of patients with an increased likelihood of progression to symptomatic myeloma. As initially hoped, measurement of serum-free light chain does not replace the measurement of Bence Jones proteins in 24-hour urine collection.

Bone Marrow Examination

Except for patients with solitary plasmacytoma, the presence of clonal plasma cells (>5%) is usually observed in all plasma cell disorders.[21] Ten or greater percentage of clonal plasma cells in the BM aspirate or biopsy (whichever is higher if both done) is required to differentiate MGUS from SMM and for diagnosis of MM. The quantitation of plasma cells should be performed with at least a 200 cell count, and confirmation of clonality is essential for diagnosis, which can be done either by immunostaining using κ/λ staining or by flow cytometry (Figs. 85-6 and 85-7). In absence of clear BM involvement, a biopsy-proven soft tissue or bony plasmacytoma is also adequate for diagnosis (Fig. 85-8). Cytogenetics and FISH studies should be performed on BM samples at the time of diagnosis and if initially confirmed as low-risk disease, then should be repeated on BM performed at the time of relapse. Although important for prognostication, cytogenetic or FISH-identified abnormalities are not adequate for diagnosing MM from MGUS or SMM. A seven-color flow cytometry panel is also now used on BM samples to detect MRD.

Investigation to Detection of End-Organ Damage

The diagnosis of a plasma cell disorder is based on the presence of a monoclonal protein and clonal plasma cells. However, the diagnosis of MGUS/SMM that currently does not require therapeutic

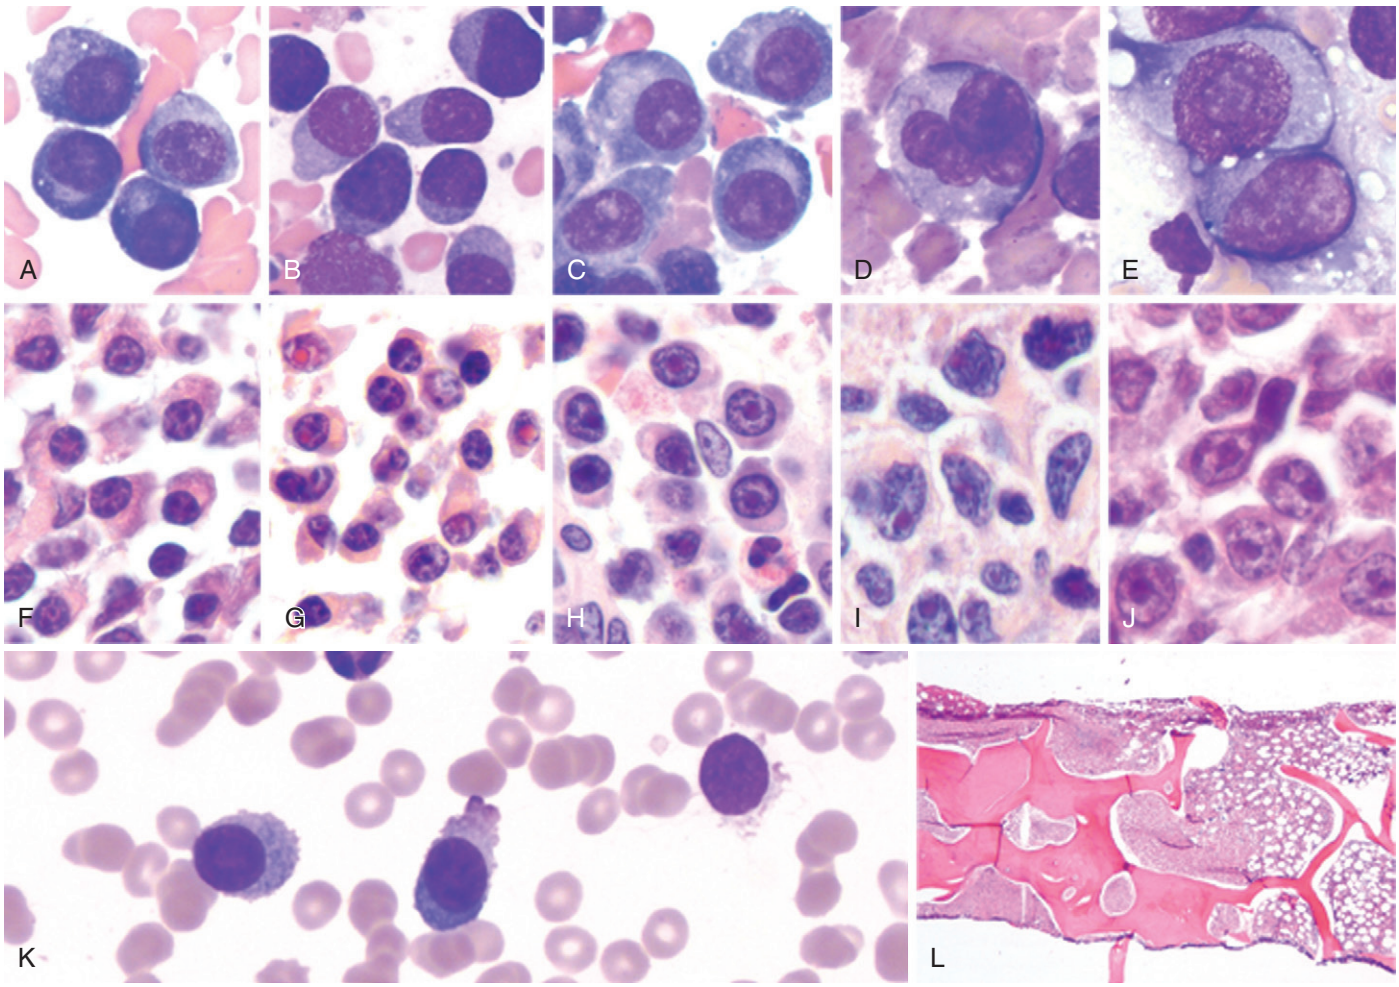

Figure 85-7 MORPHOLOGIC SPECTRUM OF NEOPLASTIC PLASMA CELLS IN MULTIPLE MYELOMA. There is significant morphologic heterogeneity in the plasma cells as seen on the bone marrow aspirate (**A** to **E**) and biopsy (**F** to **J**). The plasma cells can sometimes be fairly normal appearing (**A** and **F**); they can be "lymphocyte-like" and difficult to distinguish from lymphoplasmacytic lymphoma (**B** and **G**); they frequently can exhibit cytologic atypia with prominent nucleoli and nuclear to cytoplasmic dyssynchrony (**C** and **H**); they can exhibit anaplastic features (**D** and **I**), and they can show "blastic" features (**E** and **J**). Myeloma can also have a leukemic phase **(K)** and can be associated with osteosclerosis **(L),** as sometime seen in association with POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes).

intervention and active symptomatic MM that needs treatment is based on the detection of end-organ damage, which includes bone lesions, anemia, renal dysfunction, and hypercalcemia. The details of the diagnostic criteria are listed in Table 85-5.[21]

Radiographic Evaluation

The standard evaluation of bone lesions in myeloma is by a skeletal survey that includes plain radiographs of the entire skeleton. The presence of characteristic lytic lesions is considered diagnostic for myeloma (Fig. 85-9). Rarely, in POEMS syndrome, bone lesions are osteosclerotic. The bone lesions do not always resolve after effective therapy. Because of the absence or suppression of osteoblastic activity, the bone scan is diagnostically not a useful investigative tool in myeloma. Almost all patients with myeloma have osteoporosis caused by unbalanced osteoclastic activity. Bone mineral density (BMD) measurement by dual-energy x-ray absorptiometry helps identify osteoporosis and is considered a useful investigation. However, it is not uniformly used because all patients receive bisphosphonates, making the measurement of BMD irrelevant in therapeutic decision making. Details of various imaging modalities and their roles in myeloma diagnostics are described in Table 85-6.

Magnetic resonance imaging, computed tomography (CT), and positron emission tomography (PET) are increasingly used in MM patients. MRI allows assessment of the degree of BM involvement and judges involvement of the spinal cord. One-third of the patients have generalized hyperintensity on MRI of the skeleton, another third predominantly have focal lesions in the background of low level of BM involvement, and the another third have a mixed picture with focal lesions in the background of generalized involvement of the BM. MRI is indicated in all patients with a suspected diagnosis of solitary plasmacytoma and is indicated in SMM to identify any focal BM involvement. Identification of multiple lesions not observed on a skeletal survey allows prediction of progression and early intervention.

In symptomatic myeloma, MRI can be considered as routine evaluation to detect unsuspected focal lesions; assess the extent of involvement of the BM, especially in the spine and pelvis; and explore the possibility of cord compression. MRI is an important investigation in patients with nonsecretory myeloma and becomes a critical investigation to evaluate response. Normalization of MRI findings after achieving CR is a good prognostic feature and is being considered as one of the features to better define CR.

Computed tomography scans have been used to evaluate focal lesions and obtain fine-needle biopsy for cytologic analysis. CT scans provide a better picture of the bone component and can also be used

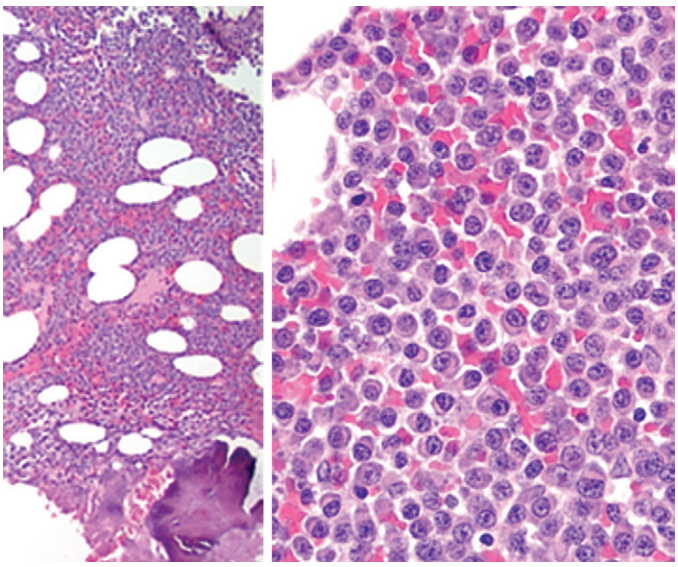

Figure 85-8 SOLITARY PLASMACYTOMA OF BONE. Bone biopsy from a 50-year-old male patient with a solitary bone lesion in the humerus. The biopsy shows some bone destruction and sheets of plasma cells which by in situ hybridization for κ and λ light-chain mRNA were found to be clonally restricted.

to judge the integrity of the bone. PET along with CT scans can be used to define the extramedullary disease as well as medullary lesions and complements MRI for follow-up of patients with nonsecretory myeloma (Fig. 85-10). Conversion of PET positivity to negativity has prognostic significance. In one prospective study in 192 patients, the presence at baseline of at least three focal lesions detected by PET/CT, a standardized uptake value (SUV) greater than 4.2, and extramedullary disease adversely affected 4-year estimates of progression-free survival (PFS; ≥3 FLs: 50%; SUV >4.2: 43%; presence of EMD: 28%) and SUV greater than 4.2 and EMD also correlated with shorter OS (4-year OS rates: 77% and 66%, respectively). In this study, post-therapy persistence of PET positivity predicted for poor outcome as compared with those with negative PET/CT (PFS, 66%; OS, 89%).

Renal Function

A serum creatinine greater than 173 mmol/L is considered to represent end-organ damage. Because absolute creatinine values do not incorporate the patient's age it may underrepresent the extent of renal dysfunction. There has been consideration of using the creatinine clearance as a more optimal diagnostic criteria. Because myeloma patients are older and have other comorbidities such as diabetes and hypertension that by themselves also affect renal function, it is necessary to establish the relationship between renal dysfunction and the plasma cell disorder (e.g., the presence of Bence Jones proteinuria may be required to support such a relationship). In the absence of Bence Jones proteinuria, a renal biopsy may be necessary. This may be even more critical in patients who otherwise fit the criteria for MGUS or SMM but have renal dysfunction. It is important to note that a renal biopsy is not required for everyone but only when the physician is uncertain as to the cause of the renal dysfunction. A biopsy is not currently required for light-chain cast nephropathy if Bence Jones protein is present as the predominant urinary protein. Other causes of renal dysfunction should be considered before attributing renal dysfunction to myeloma.

Hemogram and Serum Calcium

A standard hemogram is performed to detect anemia. The level of anemia considered to be diagnostic for myeloma is hemoglobin

Table 85-5 Diagnostic Criteria for Multiple Myeloma, Myeloma Variants, and Monoclonal Gammopathy of Unknown Significance

Monoclonal Gammopathy of Undetermined Significance or Monoclonal Gammopathy, Unattributed/Unassociated
M protein in serum <30 g/L
Bone marrow clonal plasma cells <10%
No evidence of other B-cell proliferative disorders
No myeloma related organ or tissue impairment (no end-organ damage, including bone lesions)
Asymptomatic Myeloma (Smoldering Myeloma)
M protein in serum >30 g/L *or*
Bone marrow clonal plasma cell ≥10%
No related organ or tissue impairment (no end-organ damage, including bone lesions) or symptoms
Symptomatic Multiple Myeloma
M protein in serum or urine*
Bone marrow (clonal) plasma cells* or plasmacytoma
Related organ or tissue impairment (end-organ damage, including bone lesions)
Solitary Plasmacytoma of Bone
No M protein in serum or urine†
Single area of bone destruction caused by clonal plasma cells
Bone marrow not consistent with MM
Normal skeletal survey (and MRI of spine and pelvis if done)
No related organ or tissue impairment (no end-organ damage other than solitary bone lesion)†
Nonsecretory Myeloma
No M protein in serum or urine with immunofixation
Bone marrow clonal plasmacytosis ≥10% or plasmacytoma
Related organ or tissue impairment (end-organ damage, including bone lesions)
Extramedullary Plasmacytoma
No M protein in serum or urine†
Extramedullary tumor of clonal plasma cells
Normal bone marrow
Normal skeletal survey
No related organ or tissue impairment (end organ-damage including bone lesions)
Multiple Solitary Plasmacytomas (± Recurrent)
No M protein in serum or urine†
More than one localized area of bone destruction or extramedullary tumor of clonal plasma cells, which may be recurrent
Normal bone marrow
Normal skeletal survey and MRI of spine and pelvis if done
No related organ or tissue impairment (no end-organ damage other than the localized bone lesions)
Myeloma-Related Organ or Tissue Impairment (End-Organ Damage)
Calcium levels increased: serum calcium >0-25 mmol/L above the upper limit of normal or >2-75 mmol/L
Renal insufficiency: creatinine >173 mmol/L
Anemia: hemoglobin 2 g/dL below the lower limit of normal or hemoglobin <10 g/dL
Bone lesions: lytic lesions or osteoporosis with compression fractures (MRI or CT may clarify)
Other: symptomatic hyperviscosity, amyloidosis, recurrent bacterial infections (more than two episodes in 12 months)

CT, Computed tomography; *MM,* multiple myeloma; *MRI,* magnetic resonance imaging.
*If flow cytometry is performed, most plasma cells (>90%) will show a neoplastic phenotype.
†A small M component may sometimes be present.

2 g/dL below the lower limit of normal or the patient's baseline or hemoglobin below 10 g/dL. It is necessary to exclude other causes of anemia. Circulating plasma cells are frequently observed in patients with MM. Serum calcium is measured and corrected for albumin, or in occasional cases ionized calcium is considered.

PROGNOSIS

Myeloma is a heterogeneous disease with 20% of patients having a survival time of less than 2 years, but more than 15% of patients have more than a 10-year survival time. Therefore, it is critically important to identify disease features that may allow identification of low- versus high-risk disease to better tailor therapeutic intervention. Moreover, such risk stratification permits the physician to predict life expectancy and allows development of strategies to evaluate the results of clinical trials. Various prognostic variables have been identified, including tumor burden–related factors such as β_2-microglobulin, more than three lytic bone lesions, hypercalcemia, and soluble IL-6 receptor; tumor biology–related factors such as cytogenetic or FISH-identified abnormalities, genomic changes, plasma cell–labeling index, IgA myeloma, C-reactive protein (CRP) and lactate dehydrogenase (LDH); tumor microenvironment–related factors such as BM microvessel density, serum soluble syndecan-1 levels, soluble CD16, and BM plasmacytoid DC number; patient-related factors such as age, renal failure, albumin, and performance status; and finally, treatment-related factors such as achieving CR or a very good partial response and the performance of tandem autologous transplants. Among these features, the international staging system using serum albumin and β_2-microglobulin levels; cytogenetic or FISH changes, and newer genomic correlates of outcome have been validated in a number of studies and are considered the standard of care as predictive markers in myeloma. A short list of investigations to be performed for risk stratification of MM patients is detailed in Table 85-7.[22]

International Staging System

The International Staging System (ISS) described in Table 85-8 uses simple chemical tests (serum albumin and β_2-microglobulin) to predict outcome.[23] ISS staging is able to predict both event-free survival (EFS) and OS (Fig. 85-11) and is valid irrespective of age, geographic region, study site, standard or HDT, method of albumin measurement, and use of novel agents. Although it is universally applicable, it does not include the genetic makeup of the myeloma cells and thus lacks an important consideration that drives the disease process.

Cytogenetics and Fluorescent in Situ Hybridization

By conventional cytogenetics, detection of any abnormality is considered to predict an adverse outcome. Of course, the recurrent chromosomal changes, t(4;14), t(14;16), as well as loss of 13q34 and 17p13 identified using traditional cytogenetic methods carry a poor

Table 85-6 Imaging Modalities for Disease Assessment in Myeloma

	Use	Sensitivity and Specificity	False-Negative Test Results	False-Positive Test Results
Bone scan	Not useful as a screening tool	Vary	Pure osteolytic lesions	Trauma Inflammation Benign tumor Healing
Radiography	Skeletal survey is used for standard work up of myeloma Assesses risk of fracture Useful to detect progression but not useful to determine tumor response	Low sensitivity	Low disease burden Osteopenia	Trauma Inflammation Benign tumor Healing
CT	For anatomic detail in axial skeleton Possible follow-up of tumor response especially in extramedullary disease	High sensitivity	Low disease burden	Trauma Inflammation Benign tumor Healing
MRI	Detection of spinal cord compression Can help distinguish benign from malignant vertebral compression fracture Useful to assess response and progression, especially in non-secretory myeloma	High sensitivity and specificity	Diffuse marrow infiltration	Edema
PET/CT	Useful for extramedullary disease Possible follow-up of tumor response	High specificity	Low disease burden in marrow only	After chemotherapy
Bone density	Measures osteoporosis Response to bisphosphonates	High specificity and sensitivity		Age-related osteoporosis

Table 85-8 International Staging System of Multiple Myeloma Patients

Stage	Criteria	Median Survival (mo)
I	Serum β_2 microglobulin <3.5 mg/L	62
	Serum albumin ≥3.5 g/dL	
II*	Not stage I or III	44
III	Serum β_2 microglobulin ≥5.5 mg/L	29

Data from Greipp PR, San Miguel J, Durie BG, et al: International staging system for multiple myeloma. *J Clin Oncol* 23:3412, 2005.
*There are two categories for stage II: serum β_2 microglobulin <3.5 mg/L but serum albumin <3.5 g/dL; or serum β_2-microglobulin 3.5 to <5.5 mg/L irrespective of the serum albumin level.

prognosis. Hyperdiploidy and t(11;14) translocations detected by cytogenetics have been reported in some studies to predict a favorable outcome.

As described earlier, because of a low proliferative index, cytogenetic abnormalities are only detected in a small number of patients, and interphase FISH is used to detect specific genetic aberrations. Among these abnormalities, patients with t(4;14) (15% of the patients) have a poor prognosis. In some early studies, use of bortezomib and lenalidomide has been shown to at least partly overcome poor risk associated with this abnormality. The del(17p) observed in 8% to 10% of the patients remains a poor risk feature not overcome by novel agent–based therapies.[3] Although the p53 gene resides in this region of deletion, a clear biological confirmation of its role is lacking. p53 mutations have only been detected in very small number of patients. In patients without t(4;14) or del(17p), the presence of del13 is not considered to predict a poor outcome (Fig. 85-12). Moreover, the presence of del13 observed in patients with MGUS and SMM without clear correlation with clinical outcome also raises questions about the role of del13 in myeloma progression and prognosis. As shown in Table 85-1, newer additional chromosomal changes are being identified with clinical correlation; gains of chromosome 1q, and loss of 1p are two such regions which are considered to predict a poor outcome. Additional studies are needed to confirm their significance.

High-Throughput Genomic Studies

Further analysis of genomic changes that drive the disease process has been performed using the high-throughput microarrays profiling techniques. Copy number alterations (CNAs) have been studied using either SNP[6] or CGH[7] arrays, and expression of genes has been evaluated using the expression profile arrays covering the whole expressed genome. These studies have correlated with clinical outcomes in myeloma.

The IFM-DFCI collaborative group has evaluated CNAs and correlated with survival outcomes in 192 newly diagnosed patients with

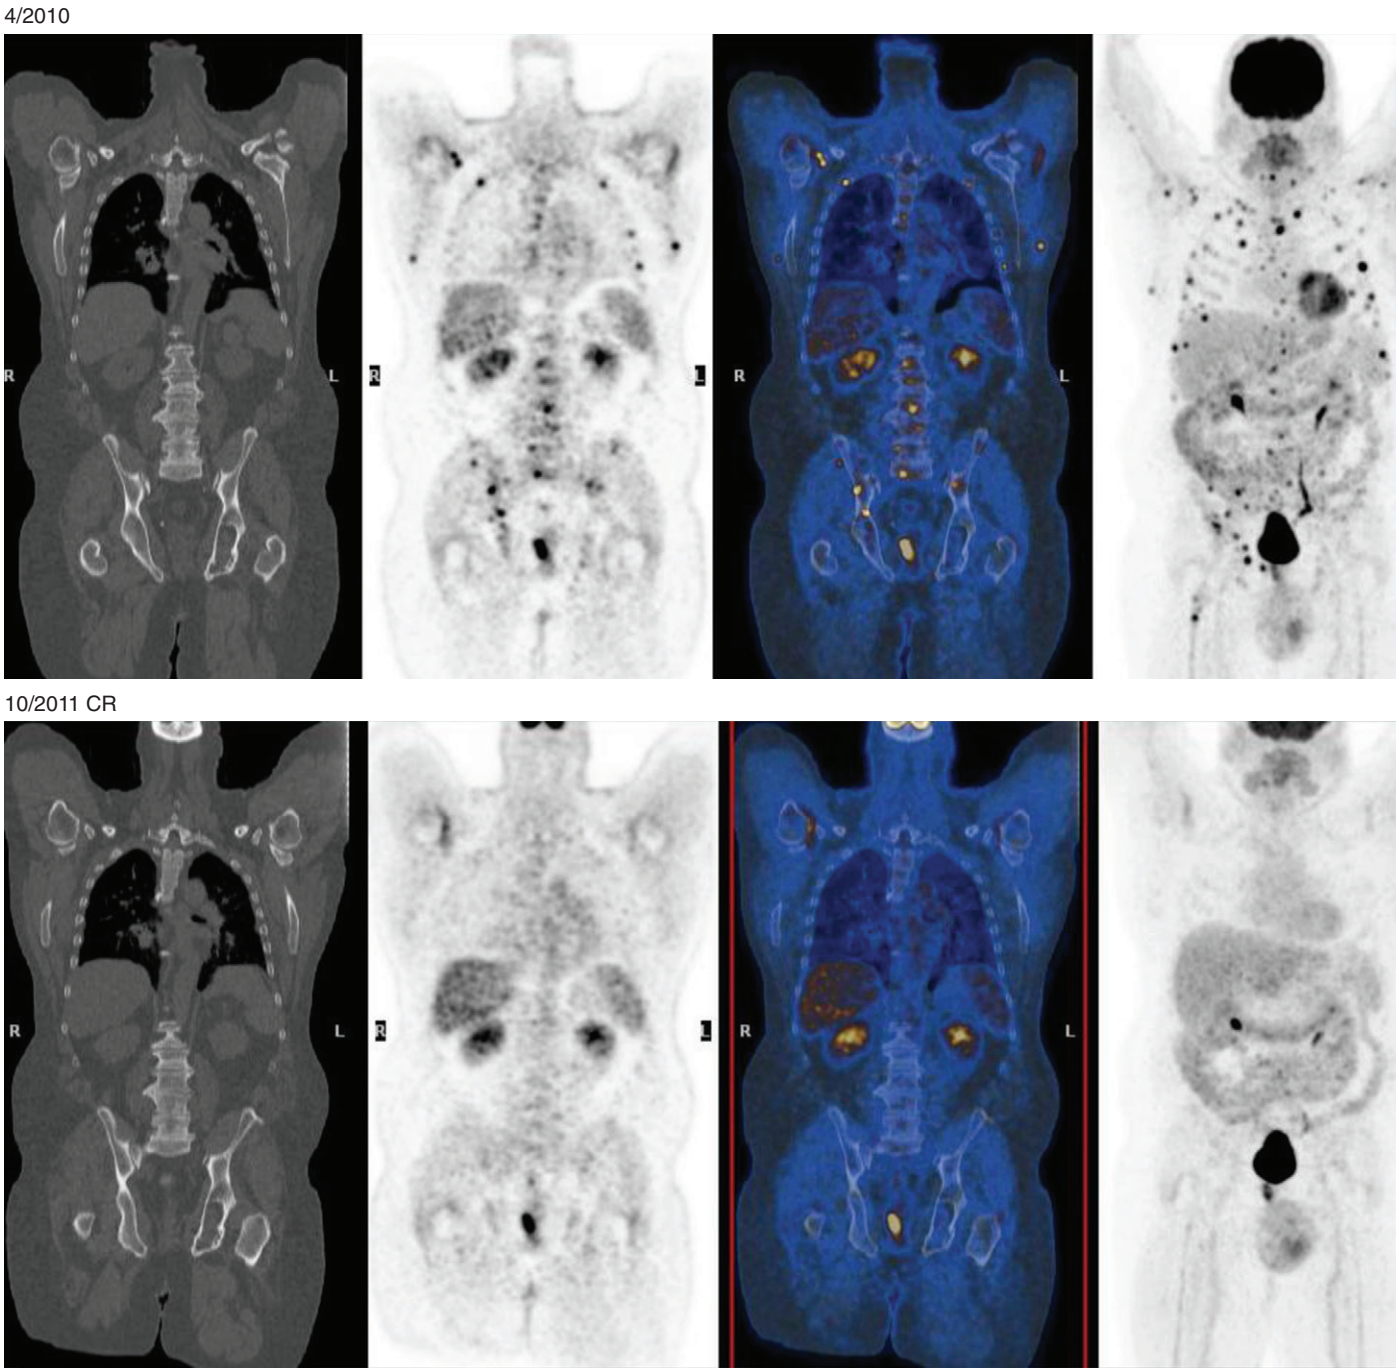

Figure 85-10 POSITRON EMISSION TOMOGRAPHY/COMPUTED TOMOGRAPHY SCAN SHOWING MULTIPLE FDG-AVID LESIONS IN THE SKELETON *(UPPER PANEL)* WITH THEIR RESOLUTION ON ACHIEVING COMPLETE REMISSION (CR) *(LOWER PANEL).* The images are CT in the *first row,* PET rear view in the *second row,* fusion of CT and PET in the *third row,* and PET front view in the *last row.*

MM who were uniformly treated. A univariate analysis identified amplifications of 1q and deletions of 1p, 12p, 14q, 16q, and 22q to be associated with a poor prognosis, but amplifications of chromosomes 5, 9, 11, 15, and 19 conferred a superior outcome. A multivariate analysis identified amp(1q23.3), amp(5q31.3), and del(12p13.31) as the most significant independent adverse markers (P <.0001). This model has been further validated in an independent cohort of 273 patients, confirming the utility of SNP profiling for prognostication.[6]

Using gene expression profiling, a 70-gene model has been proposed by the UAMS group.[24] This signature for survival identifies three groups of patients with high-, intermediate-, and low-risk disease and has been applied across various groups. Similarly, a 15-gene model is proposed by the IFM group classifying patients into two risk groups.[25] Interestingly, there is no common gene between the two models. This can be explained by differences in the treatment in different patient groups, differences in the platform used and is more likely caused by the redundancy and overlapping functions of the genes regulating various pathways. Both of the models have been better at identifying poor-risk patients. A larger scale study incorporating various genomic correlates in the future will be required to identify and validate signatures that can identify risk categories and hopefully response to therapies.

DIFFERENTIAL DIAGNOSIS

The diagnosis of MM is essentially based on laboratory results. No single or group of symptoms is pathognomonic of MM. A significant

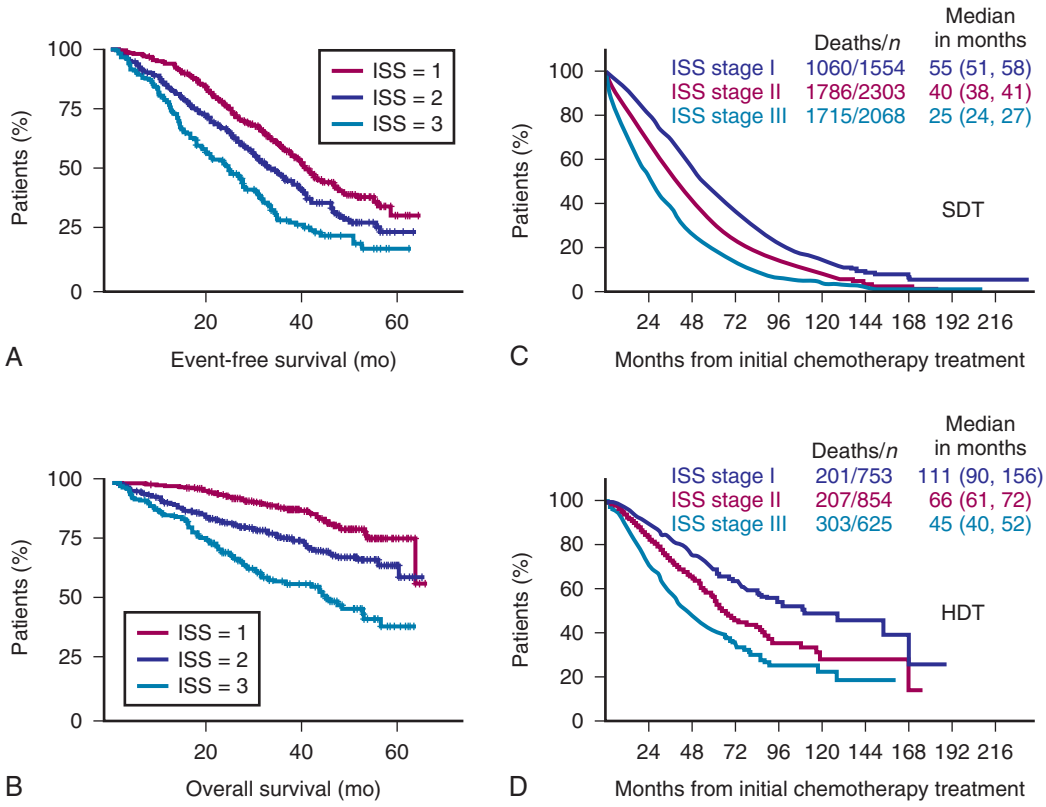

Figure 85-11 International Staging System (ISS) predicts both event-free survival **(A)** and overall survival **(B)** and overall survival with both standard-dose therapy (SDT) **(C)** and high-dose therapy (HDT) **(D)**. *(**A** and **B** from Avet-Loiseau H, Attal M, Moreau P, et al: Genetic abnormalities and survival in multiple myeloma: The experience of the Intergroupe Francophone du Myélome.* Blood *109:3489, 2007; **C** and **D** from Greipp PR, San Miguel J, Durie BG, et al: International staging system for multiple myeloma.* J Clin Oncol *23:3412, 2005.)*

number of patients remain asymptomatic, and the diagnosis is usually delayed. Most frequently, in a relatively asymptomatic patient, the investigation is carried out because of increased total protein levels, proteinuria, renal dysfunction, or bone pain. An older patient with any of these features or unexplained back pain, anemia, or recurrent infection should be screened for myeloma. Unexplained and marked elevation of an erythrocyte sedimentation rate also warrants an investigation for a diagnosis of plasma cell disorder. The diagnosis is based on two steps: first, the detection of a monoclonal protein and monoclonal plasma cells, and second, identification of end-organ damage. This is essential to differentiate early stage plasma cell disorders such as MGUS or SMM from active symptomatic myeloma. When a diagnosis of MM is suspected, investigations are carried out as detailed in Table 85-9. Evaluation for a monoclonal protein includes electrophoresis of serum proteins as well as 24-hour urine collection and serum-free light-chain measurements. Both serum protein electrophoresis and quantitative immunoglobulins are required to quantitate, and an immunofixation is important at the time of diagnosis to identify the type of paraprotein present. The BM is examined for the presence of clonal plasma cell mainly by histology but also importantly by immunostaining or flow cytometry using κ/λ staining. Determination and quantitation of clonal plasma cells is required to differentiate SMM from MGUS. Detailed investigation to look for organ damage is then undertaken to look for bony lesions, renal dysfunction, anemia, and hypercalcemia. In patients in whom hyperviscosity is suspected, in addition to measuring serum viscosity, a funduscopic examination is useful. Detailed diagnostic criteria are summarized in Table 85-5.[21]

Table 85-9 Evaluation of Multiple Myeloma Patients

Evaluation for Diagnosis Evaluation for Monoclonal Protein
Serum protein electrophoresis, immunofixation
Quantitative immunoglobulin by nephelometric method
24-hour urine collection for electrophoresis and Bence Jones protein assessment and immunofixation
Serum-free light chain and ratio
Evaluation for Clonal Plasma Cells
BM aspirate and biopsy for
Histology
Clonality by immunostaining or flow cytometry by κ/λ staining

TREATMENT

Treatment of underlying plasma cell dyscrasias is warranted when organ or tissue function is compromised. The damage to the organ or functional impairment could be caused by the underlying plasma cell clone or related to the monoclonal protein. The acronym CRAB (hypercalcemia, renal impairment, anemia, and bone disease) is helpful in this regard. Symptomatic hyperviscosity, amyloidosis, monoclonal immunoglobulin deposition disease, recurrent bacterial infections (more than two major infections), and progressive peripheral neuropathy are also indications for initiation of treatment. The constellation of polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy and the skin changes in the setting of osteosclerotic myeloma (POEMS syndrome) may present a challenging diagnosis but is always an indication for treatment.

Monoclonal Gammopathy of Unknown Significance and Smoldering Multiple Myeloma

MGUS is characterized by serum paraprotein below 3 g/dL and BM plasmacytosis below 10% and absence of amyloidosis, a solitary plasmacytoma, Waldenström macroglobulinemia, or a B-cell lymphoproliferative disorder. The diagnosis of MGUS is often incidental when a serum or urine protein electrophoresis and immunofixation are ordered as a part of a battery of tests. The test may have been ordered for evaluation of elevated globulin in the serum, proteinuria, peripheral neuropathy, osteoporosis, immune disorders, or hypogammaglobulinemia.[26,27] The rate of progression of MGUS to MM is 1% per year. These patients can be further risk stratified based on serum M spike level less than 1.5 g/dL, IgG isotype and a normal serum free light-chain ratio (Fig. 85-13). The presence of all of these factors would be low risk with only a 2% chance for progression at 20 years after eliminating competing causes of death. If one of these factors is abnormal, patients will fall into low-intermediate-risk category with 10% absolute risk of progression to myeloma at 20 years. The presence of two abnormal factors will place the patients into high-intermediate-risk group; their absolute risk of progression to MM is 18% at 20 years. Finally, when all three risk factors are abnormal, the patient falls into the high-risk category with an absolute risk of progression of 27% at 20 years.

Asymptomatic myeloma (SMM) is characterized by BM plasmacytosis of 10% or greater or serum paraprotein of 3 g/dL or greater.[26] Asymptomatic myeloma is often diagnosed after a workup for elevated total protein in the serum, proteinuria, or borderline anemia. It may also be discovered incidentally like MGUS. It has been shown that every case of MM is preceded by detection of paraprotein for a minimum of 2 years or more. The rate of progression to MM is 10% per year for the first 5 years, 3% per year for the next 5 years, and 1% per year after 10 years. Because the patient has no symptoms or

related organ or tissue impairment, no treatment intervention is recommended. Several factors have been identified that aid in categorizing patients into the different risk categories. Factors predictive of early progression include monoclonal spike of 30 g/L or greater on serum protein electrophoresis, BM plasmacytosis of 10% or greater, and abnormal free light-chain ratio (>8 or <0.125). The presence of three or more of these factors identifies patients with high risk to progression at a median time of 2 years; for intermediate risk, the median time to progression is five years; and the presence of only one of these risk factors indicates low risk with a median time to progression of 10 years. Other investigators have used other risk factors such as aberrant plasma cell population of 95% or greater by flow cytometry, reduction in uninvolved globulins, evolving myeloma, and abnormal MRI findings to stratify patients into different risk categories. Immunoparesis is also observed in MGUS and SMM. In one study, suppression of uninvolved immunoglobulin was observed in 25% of MGUS patients (18% had decreased levels of only one Ig, and 7% had low levels of two Igs) and 52% of SMM patients (22% of one Ig and 30% of both chains). In this analysis, immunoparesis was one of the independent predictors with a significant impact on PFS in MGUS and SMM.

This information has been helpful in designing clinical trials to try to delay the progression to symptomatic MM for patients in a high-risk category. A single randomized trial from a Spanish group has shown that early intervention with lenalidomide and dexamethasone in a high-risk group delays the time to progression and prevents occurrence of symptoms such as renal failure and lytic bone disease. Moreover, by preventing complications, the study showed survival advantage for those with early intervention. However, treatment intervention outside of clinical trials is still not recommended for patients with asymptomatic myeloma. No benefit has been shown for early intervention compared with treatment after the patient has progressed to symptomatic myeloma. Early intervention with thalidomide in asymptomatic myeloma has been reported to delay progression to symptomatic myeloma but was associated with peripheral neuropathy, and a survival benefit has not been shown in a randomized clinical trial.

Solitary Plasmacytoma: Medullary and Extramedullary

A diagnosis of solitary plasmacytoma requires fulfillment of each of the following criteria: histologic confirmation of clonal plasma cells at a single site; negative BM findings with absence of a clonal plasmacytosis; no distant bone involvement; and no anemia, hypercalcemia, or renal impairment. The solitary plasma cytoma could present as a single site of bony lesion (medullary) or in soft tissue outside of the bone (extramedullary). Solitary plasmacytoma of the bone is 40% more common than extramedullary soft tissue plasmacytoma. Solitary plasmacytoma of the bone is most commonly encountered in the axial skeleton (skull, spine, pelvis, ribs, and sternum), accounting for 80% of the cases; the upper and lower extremities account for 15% of the cases. Extramedullary soft tissue plasma cytomas are often associated with mucosal area of the upper aerodigestive passages (80%).

Solitary plasmacytomas are rather uncommon and account for 6% of plasma cell neoplasms. The incidence rate is 0.3 per 100,000 person years in the United States. Similar to MM, the incidence of solitary plasmacytoma increases with age; however, the median age of diagnosis was 62 years for extramedullary plasmacytomas and 65 years for solitary bone plasmacytoma compared with a median age of onset of 69 years for MM in the Surveillance, Epidemiology and End Results (SEER) database. The incidence of solitary plasmacytoma has increased by 10% from 1999 to 2004 relative to 1992 to 2008; the incidence of MM has declined by 3% during the same period.

Patients presenting with solitary plasmacytomas require a complete workup to confirm the diagnosis. They should undergo serum protein electrophoresis, serum immunofixation, serum-free light-chain assay, urine protein electrophoresis, urine immunofixation, a diagnostic BM aspiration and biopsy with flow cytometry to detect clonal plasma cells and detailed skeletal imaging that should include either a PET-CT or a skeletal survey and MRI of the spine and pelvis. One-third of the patients may present with a detectable monoclonal paraprotein in the serum, urine, or both. Persistence of the monoclonal paraprotein after local treatment is predictive of a recurrence of MM. Patients with less than 10% plasma cells in the BM biopsy may be managed for the solitary lesion initially. However, these patients will also progress to MM over the subsequent years of follow-up.

Solitary plasmacytomas are generally treated with local radiation therapy at a dose of 40 to 50 Gy. Depending on the location, small extramedullary soft tissue plasmacytomas may be treated with excision biopsy alone. Solitary plasmacytomas of the bone may require surgical intervention for stabilization followed by local radiation therapy.

The disease-free survival at 10 years is 63% for the entire population of solitary plasmacytomas in the SEER database. The disease-specific survival seemed to plateau at about 80% for extramedullary plasmacytomas compared with 50% for solitary bone plasmacytoma. Less than one-third of solitary extramedullary plasmacytoma patients died of myeloma compared with 58% of the patients with solitary bone plasmacytomas. Progression to myeloma generally occurs within 5 years from initial diagnosis. Patients presenting with medullary plasmacytomas, patients with persistence of a monoclonal paraprotein after treatment for the solitary plasmacytoma, patients with detectable low levels of clonal plasma cells in the BM, patients between 40 and 60 years of age, and patients of African American descent are at higher risk for progression to myeloma. These patients need to be followed closely for the next 5 years.

Symptomatic Myeloma

Patients presenting with symptoms caused by myeloma tumor mass such as anemia, lytic bone disease, hypercalcemia, or renal impairment (CRAB) require systemic therapy. In addition, patients with a low tumor mass but presenting with organ dysfunction caused by a paraprotein or immunodeficiency, such as monoclonal immunoglobulin deposition disease or amyloidosis of an organ, progressive peripheral neuropathy, two are more serious infections (pneumonia, bacteremia) related organ or tissue impairment (ROTI) also warrants initiation of systemic therapy.[21]

Front-line therapy for MM is often predicated on whether patient is eligible, willing, and able to proceed with HDT and SCT. The treatment given before stem cell harvest and transplantation is called induction therapy followed by consolidation with HDT and stem cell rescue. Patients not embarking on HDT are started on initial therapy for 9 to 18 months. Both groups of patients may subsequently receive maintenance therapy.

Induction Regimen and Initial Treatment

Four classes of drugs are frequently used for the treatment of patients with MM: (1) cytotoxic drugs targeting the DNA (melphalan, cyclophosphamide, carmustine [BCNU], doxorubicin, etoposide, cisplatin), and antimitotic agent vincristine), (2) glucocorticoids, (3) immunomodulatory agents (thalidomide and lenalidomide), and (4) proteasome inhibitors (bortezomib). The first two classes of drugs are considered standard chemotherapy because they have been available since the early 1960s. The latter two are called novel agents as they became available in the mid 2000s.

STANDARD CHEMOTHERAPY TREATMENTS

Chemotherapy With Stem Cell–Sparing Agents

Patients considered for stem cell harvest are generally treated with combinations that are stem-cell sparing. Before immunomodulatory agents and proteasome inhibitors became widely available, patients

were treated with pulsed dexamethasone alone or in combination with vincristine and Adriamycin (VAD) and cyclophosphamide (CVAD or CVAMP [methylprednisolone substituted for dexamethasone]).

Dexamethasone

Glucocorticoids induce apoptosis in myeloma cells. Glucocorticoids induce IkB production, which then sequesters nuclear factor kappa-B (NFκB), resulting in downregulation of IL-6 and production of other inflammatory cytokines. Dexamethasone 40 mg is administered in a pulsed fashion for 4 days, starting on days 1, 9, and 17 for the first cycle. Some studies have continued this dose and schedule every 35 days, and others have given dexamethasone on days 1 to 4, every other cycle, on a 28-day schedule. Results achieved with pulsed dexamethasone alone compare well against VAD chemotherapy and melphalan and prednisone (MP), with equivalent response rate and OS. Single-agent dexamethasone is no longer advocated as a treatment for newly diagnosed myeloma. However, under selected clinical situations, the use of pulsed dexamethasone is helpful in specific situations, including severe spinal cord compromise, hypercalcemia, and acute renal failure caused by light-chain nephropathy. While patients are on intensive dexamethasone, close monitoring for hyperglycemia and prophylaxis against bacterial, *Pneumocystis carinii* pneumonia, and fungal infection is recommended. Weight gain, mood swings, insomnia, fluid retention, proximal myopathy, and steroids psychosis are known side effects. Cataracts, osteoporosis, and the avascular necrosis of the hips are some of the long-term consequences of steroid exposure.

Vincristine, Adriamycin, and Dexamethasone

Infusional therapy with vincristine and Adriamycin with pulsed dexamethasone is an effective stem cell–sparing induction regimen. Vincristine and doxorubicin were administered by continuous infusion at the doses of 0.4 mg/day and 9 mg/m^2/day along with oral dexamethasone 40 mg/day for 4 days. After 6 to 9 cycles of VAD chemotherapy, the overall response rate (ORR) was 45% to 55%, and the complete response rate was less than 5%. There was no difference in the median PFS (18 months) or OS (3 years) compared with standard alkylating agent treatments (MP, VMCP/VBAP, VBMCP). However, if the induction therapy is followed by consolidation with high-dose melphalan and autologous SCT, substantial improvement in the PFS and OS was observed. Hair loss and the need for catheter placement to administer these vesicant agents have been important limitations on its acceptance by the patients. It is also possible to administer the daily dose of vincristine and Adriamycin as an intravenous push without loss of efficacy or increased toxicity.

Chemotherapy With Alkylating Agents

Alkylating agents melphalan and cyclophosphamide were introduced in the management of MM in the early 1960s. Since the time of introduction, they continue to play a vital role in the treatment of patients with myeloma.

Melphalan and prednisone has been the gold standard of treatment. All new combinations are benchmarked against MP. MP has been given in different doses and schedules for a minimum of 9 to 18 months. Other agents such as cyclophosphamide, carmustine (BCNU), vincristine, and Adriamycin have been successfully combined with MP (VBMCP, VBAP, and so on). Combination therapies improved the response rate but did not change the OS outcomes. MP has a response rate of 50% to 60%, a PFS of 18 months, and OS of 30 to 36 months.

In the 1960s, single agent oral cyclophosphamide and oral melphalan were compared head to head in a randomized, double-blind study and were noted to have equivalent antimyeloma activity. Cyclophosphamide is less stem cell toxic than melphalan. Cyclophosphamide in high doses (2 g/msq up to 6 g/msq) followed by filgrastim has been used for stem cell mobilization, and high doses of melphalan (200 mg/msq) are routinely used as the conditioning regimen in conjunction with autologous SCT. There is a higher incidence of secondary leukemia associated with chronic melphalan therapy (17.4% at 50 months) leading to abandonment of melphalan as maintenance therapy and limiting the exposure to 1 year or less.

Novel Agents

Immunomodulatory Drugs

Thalidomide has both selective cytokine inhibitory activity (SelCID) as well as immunomodulatory (IMiD) activity. A series of compounds were derived from thalidomide: drugs with enhanced immunomodulatory activity (IMiD) or selective cytokine inhibitory activity (SelCID). Immunomodulatory drugs stimulate T-cell proliferation and IL-2 and interferon-γ production, inhibit TNF-α and IL-1β production, and increase IL-10 production by peripheral blood mononuclear cells. Both lenalidomide and pomalidomide are 100- to 1000-fold more potent than thalidomide with respect to their immunomodulatory activity. These molecules modulate the adhesion molecules expressed by the myeloma cells, thereby reducing the interaction between the myeloma cells and stromal cells; they downregulate secretion of inflammatory cytokines, including IL-6, TNF-α, and IL-1β by the stromal cells. IL-6 is a growth factor for myeloma cells. They also downregulate the secretion of VEGF and basic fibroblast growth factor (b-FGF) production by the myeloma cells and stromal cells and thereby reduce the microvessel density in the BM microenvironment. IMiDs stimulate the T lymphocytes to produce IL-2 and γ-interferon and thereby activate NK cells and CD8-positive T cells that are cytotoxic to myeloma cells.

More recently, additional insights into the mechanism of action of thalidomide and IMiDs has been gained with the discovery of thalidomide-binding protein cereblon (CRBN). Human CRBN was originally identified as a candidate gene for an autosomal recessive form of mild mental retardation and is located on chromosome 3 at 3p26.2. It encodes a 442–amino acid protein that is highly conserved from plants to humans. CRBN is widely expressed in the testes, prostate, ovary, placenta, spleen, liver, pancreas, kidneys, small intestine, colon, lungs, skeletal muscle, peripheral blood leukocyte, brain, and retina, where CRBN is located in the cytoplasm, nucleus, and peripheral membranes. Thalidomide interacts directly with CRBN and indirectly with damaged DNA-binding protein 1 (DDB1) through its interaction with CRBN. CRBN forms an E3 ubiquitin ligase complex with DDB1 and Cul4A, affecting downstream targets including interferon regulatory factor 4 (IRF4). CRBN likely plays an important role in binding, ubiquitination, and degradation of factors involved in maintaining functional myeloma cells. Drug resistance to IMiDs is associated with depletion of CRBN.

Thalidomide

Thalidomide–dexamethasone (TD) has been shown to be superior to dexamethasone alone in an international randomized phase 3 clinical trial. TD has an ORR of 63% and PFS of 14.9 months compared with 46% and 6.5 months with pulsed dexamethasone; however, there was no difference in the OS at a median follow-up of 18 months. There was no difference between TD versus VAD as a pretransplant induction regimen. Likewise, TD had a slightly inferior survival outcome compared with MP as first-line therapy in elderly patients. Thalidomide does not overcome poor prognostic genetic features. TD is no longer considered optimum treatment for newly diagnosed patients with MM. Thalidomide is generally prescribed at 200 mg/day. No maximally tolerated dose has been defined for thalidomide; doses as high as 800 mg/day have been used. Major side effects of thalidomide include irreversible peripheral neuropathy that develops after exposure for a period of 6 months or longer. Other

Treatment of Relapsed Multiple Myeloma

- Ensure that the patient has a relapse requiring intervention.
 - The conversion from a negative immune-fixation analysis to a positive study result is not an indication to initiate salvage therapy. A clear clinical relapse with new or increased evidence of end-organ damage or a substantial or aggressive biochemical relapse as defined by criteria for progressive disease are indications for the initiation of treatment.
- Selection of treatment depends on prior therapy received.
 - Lenalidomide based
 - Initial treatment with bortezomib–thalidomide
 - Underlying peripheral neuropathy
 - Lenalidomide should be used with caution in patients with renal dysfunction with appropriate dose adjustment
 - Bortezomib based
 - Initial treatment with immune-modulatory agents
 - Renal dysfunction
 - Poor hematopoietic reserve
 - Prolonged response (>12 mo) to prior therapy with bortezomib
 - Thalidomide based
 - Prior bortezomib–lenalidomide
 - Renal impairment
 - Poor hematopoietic reserve
 - Chemotherapy with or without a novel agent combination
 - Progressed on novel agents
 - Rapid, aggressive relapse with high LDH or extramedullary plasmacytomas
 - Salvage transplant
 - In transplant-eligible patients, one needs to consider if an SCT was deferred as initial therapy or if the patient had a prolonged remission (>3 years) after the first transplant or has poor hematopoietic reserve and stored stem cells. Transplant may also be considered as a way to reestablish hematopoiesis in select cases
- Special considerations
 - Rapid relapse, or relapse at multiple sites, or extramedullary sites: chemotherapy with or without combination therapy with a novel agent
 - CNS relapse: radiation therapy for localized disease; intrathecal chemotherapy for positive CSF cytology; along with systemic therapy as indicated
 - Poor performance status and hematopoietic reserve: oral therapy with low-dose daily cyclophosphamide, thalidomide, and prednisone
 - Prior drug exposure and associated toxicity: consider the presence of neuropathy, cytopenias, and advanced and renal dysfunction to decide on agents, their schedules, and their doses
- Entry in clinical trials

CNS, Central nervous system; *CSF,* cerebrospinal fluid; *LDH,* lactate dehydrogenase; *SCT,* stem cell transplantation.

serious side effects include DVT and pulmonary embolism when combined with dexamethasone and does require thromboprophylaxis. For patients with no additional risk factors for developing a DVT prophylaxis with a low-dose aspirin (81-100 mg) daily is adequate. Other clinically significant side effects include severe constipation, severe bradycardia, and skin rash. Results with thalidomide combinations in relapsed and newly diagnosed patients are summarized in Tables 85-10 and 11.

Thalidomide has been used in combination with other drugs in newly diagnosed MM patients. Six large randomized clinical trials have been conducted combining melphalan and prednisone with or without thalidomide. Meta-analysis of these six large studies with primary data has shown MPT to be superior to MP alone; the ORR improved by 22% (59% vs. 37%), PFS improved by 5 months (20 months vs. 15 months), and OS improved by 6 months (39 months vs. 33 months) (Table 85-12). MPT is an acceptable front-line treatment for patients older than the age of 65 years. Side effects were higher on the MPT arm. DVT occurred in 6% to 12% versus 1% to 4% of patients, peripheral neuropathy occurred in 6% to 23% of patients versus 0% to 5% of patients, and discontinuation of treatment occurred in 41% to 45% of patients versus 6% to 11% of patients with MP alone.

Thalidomide, Adriamycin, and dexamethasone (TAD) induction therapy followed by SCT and subsequent maintenance with thalidomide was noted to be superior to VAD induction followed by transplant and interferon maintenance in a large randomized trial by the HOVON.

Oral Regimens

Cyclophosphamide, thalidomide, and dexamethasone (CTD) was compared with infusional CVAD chemotherapy for patients eligible for HDT in a large multicenter, randomized phase 3 trial conducted in the United Kingdom (MRC myeloma IX trial). The CTD regimen consisted of cyclophosphamide 500 mg weekly, thalidomide 100 mg/day, and dexamethasone 40 mg for 4 days every other week. The induction chemotherapy was given for a minimum 6 cycles and up to 9 cycles or until maximum response. The postinduction ORR was significantly higher with CTD versus CVAD (82.5% vs. 71.2%; $P < .0001$); likewise complete response rates were also higher with CTD (13% vs. 8.1%; $P = .0083$). The superior response rate of CTD was maintained after autologous SCT; posttransplant CR (50% vs. 37.2%; $P = .00052$). With a median follow-up of 47 months, there was no difference in PFS or OS between the two groups. This establishes CTD as an acceptable induction therapy before transplant.

For elderly patients and patients otherwise ineligible for HDT, CTD was compared with MP. The dose of cyclophosphamide was 500 mg weekly, thalidomide was 50 mg/day, and dexamethasone was 20 mg for 4 days every other week. Both arms were oral regimens. CTD therapy was associated with a superior ORR (63.8 vs. 32.6%; $P < .0001$), and complete response rate (13.1% vs. 2.4%) and very good partial response (VGPR) (16.9% vs. 1.7%). After a median follow-up time of 44 months, PFS and OS were similar between the groups. CTD was associated with higher rates of thromboembolic events, constipation, infection, and neuropathy. This study also illustrated that thalidomide was incapable of improving the outcome of patients with unfavorable genetic markers.

Lenalidomide

Lenalidomide–dexamethasone is an effective combination therapy for the treatment of previously untreated symptomatic myeloma patients. A large open-label, phase 3 randomized trial comparing lenalidomide plus high-dose dexamethasone or lenalidomide plus weekly dexamethasone conducted by the Eastern Cooperative Oncology Group established lenalidomide and dexamethasone as a simple oral regimen that could be used as an induction therapy before transplant or as a first-line therapy without SCT. Administration of lenalidomide 25 mg/day for 3 weeks on and 1 week off along with dexamethasone 40 mg in a pulsed fashion (days 1-4, 9-12, and 17-20) for the first 4 cycles only (high-dose dexamethasone arm) gave a higher response rate of 79% compared with weekly dexamethasone 40 mg (low-dose dexamethasone arm, 60%); however, the high-dose dexamethasone arm was associated with a higher incidence of infection and venous thromboembolism and an inferior 1-year survival rate (87%) compared with the low-dose dexamethasone arm (1-year survival rate, 96%). However, with longer follow-up there was no survival difference between the two arms. Landmark analysis at 4 months has projected a 3-year survival rate of 92% for patients who electively received high-dose melphalan and SCT after 4 cycles of induction

therapy; patients who continued on primary therapy had a projected 3-year survival rate of 79%. A retrospective case-control study from a single institution comparing lenalidomide–dexamethasone versus thalidomide–dexamethasone revealed that lenalidomide–dexamethasone was better tolerated, with a higher ORR (80% vs. 61%), VGPR (34% vs. 12%), improved PFS (27 months vs. 17 months), and OS. Addition of clarithromycin to lenalidomide and low-dose dexamethasone resulted in an ORR of 90% and VGPR of 74% and CR of 39% of patients. Thus lenalidomide–dexamethasone is an excellent induction regimen for first-line therapy for newly diagnosed myeloma patients. Results with lenalidomide combinations in relapsed and newly diagnosed patients are summarized in Table 85-13 and 85-14. Lenalidomide has also been combined with MP with its continued use as maintenance (MPRR), and as shown in Table 85-15, it provides superior response and PFS as compared with MP alone.

Bortezomib

Bortezomib, a boron-containing dipeptide, is the first proteasome inhibitor to be introduced for the treatment of MM. Bortezomib is

a specific and reversible inhibitor of the 26S proteasome, binding to the chymotrypsin-like enzymatic site. The incomplete and transient inhibition of the proteasome results in apoptosis of myeloma cells by activation of both caspases 8 and 9 while sparing normal tissue. There is downregulation of NFκB in the myeloma cells, osteoclasts, and surrounding stromal cells. This results in decreased release of inflammatory cytokines in the BM milieu such as IL-6. Bortezomib not only arrests osteclastic activity by reducing sRANKL, decreases c-terminal cross-linking telopeptide of collagen type-I (CTX), and serum levels of tartrate-resistant acid phosphatase (TRAP) type-5b but also induces osteoblasts by decreasing serum dickkopf-1 (Dkk1) as reflected by an increase in bone-alkaline phosphatase and osteocalcin, irrespective of treatment response.

Bortezomib as a single agent induces CR in 10% and results in an ORR of 27% in newly diagnosed myeloma patients; bortezomib is not recommended as a monotherapy. Bortezomib and dexamethasone (B-D) is an excellent induction regimen with an ORR of 88% and CR+ VGPR rate of 19% and 1-year survival rate of 87%. Randomized trial has shown B-D to be superior to VAD as an induction regimen with higher complete response rate (15% vs. 6%) and ORR (79% vs. 63%).[28] After autologous SCT, there is continued advantage for the B-D arm (VGPR or better 54% vs. 37%). Median PFS was 36 months versus 30 months, and 3-year survival rates were 81% versus 77% with a median follow-up of 32 months. Results with bortezomib combination therapy, including relapsed and newly diagnosed patients, are summarized in Tables 85-16 and 85-17. Bortezomib has also been combined with melphalan and prednisone (MPV), and as shown in Table 85-15, after 5 years of follow-up, it provides superior ORR, CR, PFS, and OS compared with MP alone.

Combination of Three or Four Classes of Drugs

It is possible to combine drugs from different classes with nonoverlapping toxicities without compromising the dose to maximize the antitumor effect and eliminate potentially resistant clones to prolong the remission duration. Generally, three-drug combinations have been shown to give the highest ORR and VGPR compared with two-drug regimens (VCD, VRD, VTD).[29,30] Fig. 85-14 summarizes the results with two-, three-, and four-drug regimens and suggests improved responses and a higher incidence of CR using a three-drug regimen (RVD, VCD) with apparently no clear benefit of adding a fourth agent yet. Similar results are also depicted in Fig. 85-14 with MP-based regimens.

Table 85-16 Bortezomib Regimens in Relapsed or Refractory Multiple Myeloma

High-Dose Therapy and Consolidation

Tim McElwain introduced high-dose intravenous melphalan for the treatment of MM in 1983. A dose-response effect for melphalan was quite evident in MM. In the 1980s and 90s, HDT with stem cell support was increasingly used to treat younger patients (65 years and younger).

Source of Stem Cells

In the 1980s, BM was harvested from the patient under general anesthesia. This approach has been completely supplanted by the use of peripheral blood stem and progenitor cells. Autologous BM transplant was associated with delayed hematopoietic recovery by 1 week compared with mobilized blood stem cells, resulting in a higher

Treatment of Newly Diagnosed Multiple Myeloma

Confirm that the patient has symptomatic myeloma. Patients with MGUS or SMM should not be treated outside of a clinical trial.

Perform risk stratification using ISS staging, FISH, or cytogenetics, and assessment of renal function and measurement of LDH level to develop long-term plan based on estimate of prognosis. Although initial treatment is not affected by risk category, later consideration of more aggressive consolidation or use of allogeneic SCT in eligible patients can be considered in high-risk younger patients.

Induction: Both transplant-eligible and ineligible patients can be treated with a triple-drug regimen (bortezomib and dexamethasone with lenalidomide, with thalidomide or cyclophosphamide, *or* cyclophosphamide, thalidomide, dexamethasone) for 3 to 6 cycles before transplant or 9 to 12 months for transplant-ineligible patients. For transplant-ineligible patients, additional options include a two-drug regimen (dexamethasone with lenalidomide, with bortezomib, *or* with thalidomide) *or* melphalan containing regimen such as melphalan with prednisone in combination with any of the newer agents, MPT, MPV, or MPR.

Drug Selection should be influenced depending on patient characteristics.

- Renal dysfunction: agents that can be considered for use are bortezomib, cyclophosphamide, thalidomide, and dexamethasone (VCD or VTD)
- Neuropathy: agents that can be considered for use are lenalidomide, cyclophosphamide, and dexamethasone
- Advanced age: consider dose or scheduled attenuation
- Convenience: use of oral vs. intravenous agent regimen

Transplant-eligible patients can undergo a single autologous transplant with melphalan with a second autologous transplant being optional depending on the overall response or on the protocol in which the patient is participating.

Maintenance: After transplant or optimal induction therapy (to best response), patients can receive maintenance with thalidomide, lenalidomide, or bortezomib. For high-risk patients, both bortezomib and lenalidomide or thalidomide combination can be used. Selection can be influenced based on their induction regimen.

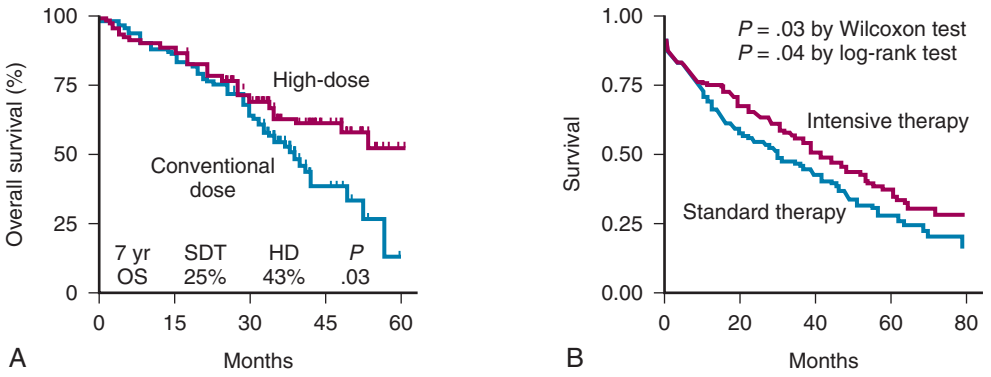
Improving complete response rates is a key goal of current trials, but patients can live a long time with residual paraprotein.

FISH, Fluorescent in situ hybridization; *ISS,* International Staging System; *LDH,* lactate dehydrogenase; *MGUS,* monoclonal gammopathy of unknown significance; *MPR,* melphalan, prednisone, lenalidomide; *MPT,* melphalan, prednisone, thalidomide; *MPV,* melphalan, prednisone, bortezomib; *SCT,* stem cell transplantation; *VCD,* bortezomib, cyclophosphamide, dexamethasone; *VTD,* bortezomib, thalidomide, dexamethasone.

transplant-related morbidity and mortality rate of 10% compared with 2% with peripheral blood progenitor cells. Stem cells can be mobilized with chemotherapy alone, chemotherapy and growth factor (G-CSF or GM-CSF), or growth factors alone (G-CSF, G-CSF plus plerixafor). The degree of tumor cell contamination in the peripheral blood stem cell product has had no influence on transplant outcome. Ex vivo manipulations to eliminate tumor cells within the graft have not resulted in any improvement in the depth of response, PFS, or OS. It is preferable to use stem cell–sparing agents as induction therapy before stem cell harvest. Alkylating agent exposure and lenalidomide exposure should be limited to ensure adequate stem cell harvest and complete hematopoietic recovery after transplantation. It is preferable to collect stem cells after the achievement of best antitumor response to induction therapy to minimize tumor cell contamination.

AUTOLOGOUS STEM CELL TRANSPLANTATION

Single High-Dose Therapy With Stem Cell Transplantation Rescue



Several prospective, randomized clinical trials have been performed to define the role of HDT and SCT as a component of front-line therapy for MM patients in the 1990s. Two studies, the IFM 90[31] and MRC VII,[32] reported the superiority of HDT and SCT with respect to response rate, PFS, and OS and led to widespread use of HDT and SCT for patients up to the age of 65 years (Fig. 85-15).[33] However, other studies did not show a survival advantage but did show improvements in the response rate and PFS. One such clinical trial was conducted by the French myeloma autograft group in patients between the ages of 55 and 65 years (MAG 90) and showed a higher response rate (CR + MRD, 36% vs. 20%) and a trend for improved PFS (EFS, 25.3 vs. 18.7 mo; $P = .07$) in favor of the HDT arm but no difference in the OS. The Spanish trial gave induction therapy VBMCP/VBAD for 4 cycles at five weekly intervals; subsequently, responding patients were randomized between HDT and continuation of standard chemotherapy for 8 additional cycles of VBMCP/VBAD. Although the HDT arm had a higher CR rate, there was no difference in PFS or OS. Another trial conducted by the U.S. Intergroup Trial also allowed for induction therapy followed by a randomization of all patients to a single autotransplant versus continued VBMCP therapy for 1 year. This study did not show a difference in the OS between the two arms. In this study, the patients on the standard treatment arm were allowed to receive HDT and SCT after relapse. Results of five large randomized trials comparing standard-dose chemotherapy (SDT) with HDT are summarized in Table 85-18.

Another randomized phase 3 trial in patients younger than the age of 56 years evaluated the role of early versus late transplantation (MAG 91); this study showed that there was no difference in OS. However, the investigator showed that early application of HDT resulted in a prolonged PFS compared with the standard chemotherapy arm; therefore, the time without symptoms, additional treatment, and treatment toxicity was favorable when HDT was applied as part of the initial therapy. This allowed for flexibility in the timing of transplantation to suit the patient's clinical situation and preference.

A meta-analysis of primary data obtained from the three French studies (IFM 90, MAG 90, and MAG 91) showed no difference in OS between the standard therapy and HDT arms. Likewise, another meta-analysis performed on data culled from nine randomized clinical trials reported in the literature showed no survival benefit for HDT and SCT. In direct contrast to the meta-analysis from the Swedish Cancer Registry and SEER, data have shown improvement in 5-year relative survival ratios for younger patients primarily because of the introduction of HDT and SCT in the 1990s.

On the presumption that a single alkylating agent therapy at maximum tolerated doses may not be adequate for disease eradication, Barlogie pioneered a tandem transplant approach as part of his total therapy approach for the treatment of myeloma in 1989 (total therapy 1) and reported promising results without increased treatment-related morbidity or mortality. Single HDT resulted in a CR rate well under 25% in most trials. Addition of TBI, busulfan, cyclophosphamide, or BCNU (BEAM) to melphalan did not result in better outcome. Therefore, investigators tried to improve the results by providing a second consecutive high-dose melphalan and SCT (tandem transplantation).

Four large randomized clinical trials have compared the role of tandem autotransplantation against a single episode of HDT and SCT (Table 85-19). All four studies showed improvement in the depth of response (VGPR) after a tandem transplant; three of the four studies showed improvement in PFS, but only one study showed an improvement in the OS. The French trial, IFM 94,[34] showed the benefit of a second transplant only for patients not in VGPR or better after the first transplantation. In the era of novel agents, a VGPR or better can be obtained before transplantation; therefore, a second transplant is seldom used outside of a setting of a clinical trial (Fig. 85-16).

Proportion alive	30 mo	45 mo	60 mo	No. at risk

†Significant difference.

In the era before introduction of novel agents, the induction regimen had only a minimal role because complete responses were uncommon (<5%) with high-dose dexamethasone or VAD chemotherapy. Thus HDT played a critical role in achieving a favorable CR and VGPR rates and prolonged durability of unmaintained responses. The availability of novel agents has dramatically changed this paradigm. Novel agents have improved VGPR or better before SCT, allowing for posttransplant consolidation and maintenance. Whether novel agents can supplant HDT and SCT is an important question that has yet to be answered.

Induction Therapy With Novel Agents

Randomized clinical trials have shown that thalidomide–dexamethasone is equivalent to VAD chemotherapy. The Dutch HOVON 50 trial compared thalidomide during the induction phase and as maintenance after HDT and SCT. TAD chemotherapy was superior to VAD chemotherapy based on overall response and quality of response before and after HDT and SCT. In addition, maintenance with thalidomide improved the PFS and resulted in a trend toward improved OS. Lenalidomide and dexamethasone have been shown to be useful as an induction regimen before transplantation. But no formal randomized clinical trial has been performed comparing this combination with conventional chemotherapy. Exposure to lenalidomide should be limited to 4 to 6 cycles because it compromises stem cell mobilization.

Bortezomib-Based Induction

Bortezomib–dexamethasone was superior to VAD chemotherapy as an induction regimen. There was improvement in CR and VGPR before and after transplantation, and there was a trend for prolonged PFS but no difference in the OS.[28] The lack of impact on PFS and OS is perhaps attributable to limited bortezomib exposure to a maximum of 4 cycles during the induction phase.

Table 85-19 Single Versus Double ASCT for Newly Diagnosed Multiple Myeloma

Study	ASCT	Patients *(n)*	CR (%)*	Median EFS (mo)	Median OS (mo)

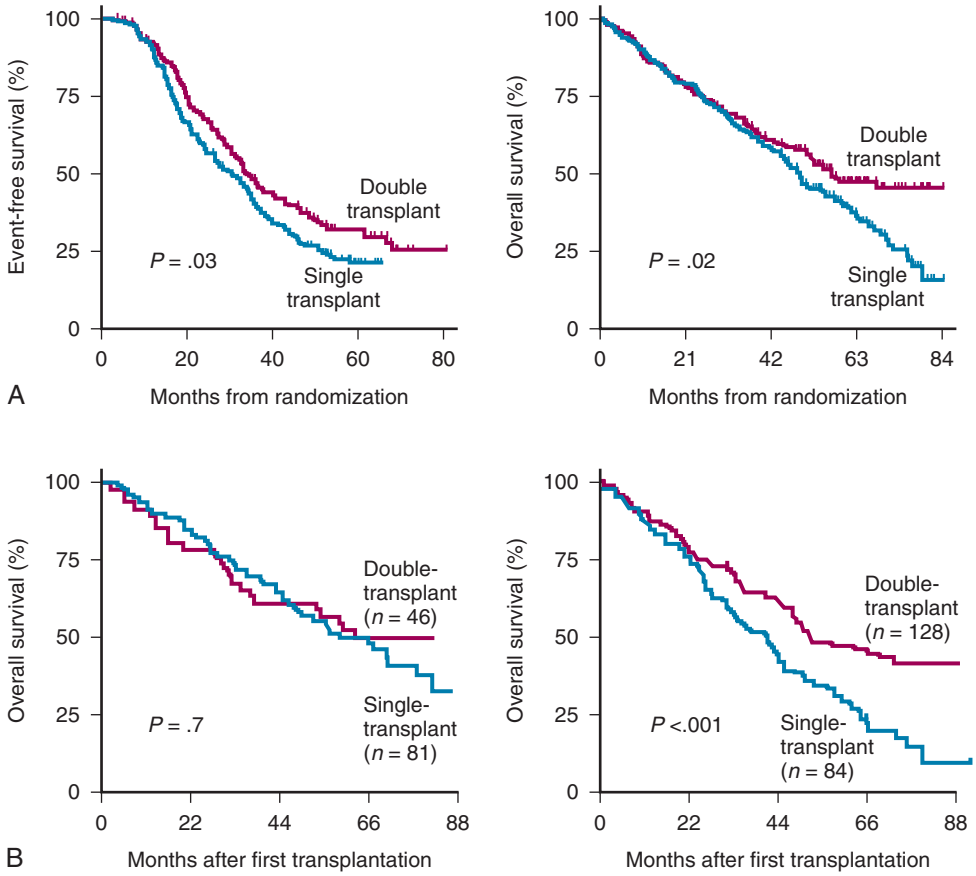

Figure 85-16 A, IFM-94 (Intergroupe Francais de Myelome 94) trial comparing a single versus tandem high-dose therapy (HDT). A total of 399 patients were randomized to a single HDT with melphalan 140 mg/m^2 plus total-body irradiation (800 cGy) versus first HDT with melphalan 140 mg/m^2 and subsequent second HDT with melphalan 140 mg/m^2 plus total-body irradiation (800 cGy). Superior event-free and overall survival were noted with tandem HDT. **B,** A subgroup analysis reveals that the survival benefit was observed in those patients not achieving a very good partial response (VGPR) after first transplant *(right)* and not in those with VGPR after first transplant *(left). (From Attal M, Harousseau JL, Facon T, et al: InterGroupe Francophone du Myélome: Single versus double autologous stem-cell transplantation for multiple myeloma.* N Engl J Med *349:2495, 2003.)*

Combining bortezomib with immunomodulatory drugs further improves the outcome before and after SCT. In a large randomized clinical trial of 480 patients conducted by the GIMEMA Italian myeloma network, VTD was shown to be superior to PD for induction therapy and for consolidation after tandem transplantation. VTD induction therapy significantly improved the rate of complete or near-complete response before the transplantation. This higher response rate continued after tandem transplantation and was further augmented by 2 cycles of VTD consolidation as opposed to TD posttransplantation. This increase in the depth of response has translated into a superior PFS. However, increased neuropathy was encountered by the patients on the VTD arm. The French investigators reduce the dose intensity of VTD and confirmed in another randomized trial that 4 cycles of VTD were to be superior to 4 cycles

of bortezomib and dexamethasone as an induction regimen before transplantation.[35] There was less neuropathy caused by the adjustment of bortezomib and thalidomide doses. The Spanish group compared TD, VTD, and multiagent chemotherapy as induction therapy and showed that VTD was superior after transplantation. The patients were further randomized to maintenance therapy with VP versus VT, with no difference in the outcome being observed. Results from two large studies using HDT with more than 7 and 12 years of follow-up are shown in Fig. 85-17, suggesting a possibility of a tail in the survival curve with more than 10% to 20% patients remaining disease free or alive beyond 10 years, suggesting a possibility for long-term survival in myeloma.

Allogeneic Stem Cell Transplantation

Allogeneic SCT offers a potential for cure for patients with MM that is mediated by a graft-versus-myeloma effect, tumor-free graft, and potential for donor lymphocyte infusion to combat the residual or recurrent disease. However, the role of allogeneic SCT in MM is limited. Patients are generally older (more than 75% of the patients are older than the age of 55 years), often presenting with comorbidities such as renal impairment, diastolic dysfunction of the heart, and restrictive lung disease. The underlying immunodeficiency associated with this disease is worsened by posttransplant immunosuppression, resulting in a high transplant-related mortality rate with standard myeloablative conditioning regimens. Relapse after allogeneic SCT contributes to the modest efficacy of this approach. Although it could be shown that there are graft-versus-myeloma effects with sustained molecular remissions, it has been difficult to induce graft-versus-myeloma effects while avoiding graft-versus-host disease (GVHD). There have been no convincing survival data to support widespread use of allogeneic SCT outside of a clinical trial.

There has been improvement in 6-month and 2-year survival rates since 1994 compared with the prior era. This improvement in the European Bone Marrow Transplant Registry was attributed to better supportive care measures and patient selection. Reduced-intensity conditioning regimens, with reduction in immediate transplant-related mortality and stable engraftment and use of peripheral blood progenitor cells from the donors with their rapid engraftment kinetics renewed interest in the use of allogeneic SCT for MM. Bensinger et al reported on the long-term results of allogeneic transplantation for MM at the Fred Hutchinson Cancer Research Center spanning 34 years Bensinger et al. Bone Marrow Transpl. 2012:1-6. Among the 144 patients undergoing ablative conditioning regimens, the 2-year, nonrelapse transplant mortality rate was 55%; major causes of death included fungal and viral infections, acute respiratory distress syndrome, acute GVHD, and multiorgan failure. The 2-year non–transplant-related mortality rate was 18% among the recipients of nonablative conditioning regimens; the causes of death were mostly chronic GVHD and progressive disease. The 10-year OS rate was 15% for myeloablative regimens compared with 35% for nonmyeloablative regimens. The incidence of acute GVHD was similar (65% + 2%), but the incidence of extensive chronic GVHD was 27% for ablative regimens compared with 67% for nonablative regimens (Table 85-20).

Several studies reported having combined the tandem autologous transplantation approach with mini allogeneic SCT. The Italian group reported superior outcomes for patients receiving an autograft–allograft protocol compared with patients receiving tandem autograft protocols.[36] At a median follow-up time of 46 months, the median OS had not been reached for patients receiving auto–allo transplants compared with 58 months for tandem autotransplants; the EFS was 43 and 33 months, respectively, for the two groups (see Table 85-20). The French group subjected patients with high-risk (β_2-microglobulin >3 mg/L and chromosome deletion 13) to tandem auto transplants or auto–allo transplants based on the availability of human leukocyte antigen–compatible sibling donors. On an intent-to-treat basis, there was no difference in EFS or OS with the trend for better OS in patients treated with tandem autologous SCT. In a recently completed BMT-CTN trial in the United States, there was no difference in outcome between auto–mini allo transplant and tandem autologous transplantation. To increase the effect of community of donor lymphocytes against the tumor cells, vaccination strategies are currently being pursued (Fig. 85-18).

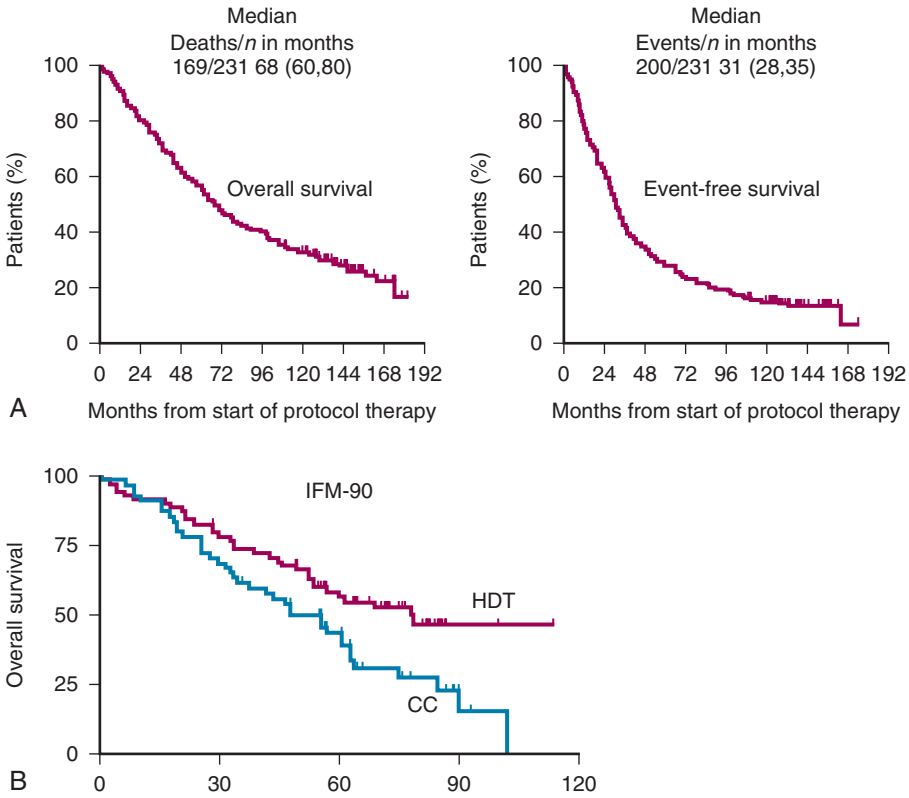

Figure 85-17 **A,** Kaplan-Meier survival estimate in patients receiving total therapy I regimen with tandem transplants after over 12 years of median follow-up (n = 231). There appears to be a plateau in the curve beyond 10 years in event-free survival (EFS). Overall survival (OS) at 10 years is 30%, median progression-free survival (PFS) is 30 months, and median OS is 68 months. **B,** Kaplan-Meier survival estimate in patients treated in the IFM-90 (Intergroupe Francais de Myelome 90) study with patients receiving standard-dose therapy (SDT) versus high-dose therapy (HDT) and single transplant after more than 7 years of median follow-up (n = 200). PFS = 18 vs. 28 mo. Median OS = 44 vs. 57 mo. *(**A** from Barlogie B, Tricot GJ, van Rhee F, et al: Long-term outcome results of the first tandem autotransplant trial for multiple myeloma.* Br J Haematol *135:158, 2006. **B** from Harousseau LL: Autologous transplantation for multiple myeloma.* Ann Oncol *19:vii, 128, 2008.)*

Syngeneic Transplantation

Results of syngeneic transplantation are superior to those of autologous and allogeneic SCT. The results are better than autologous transplantation because of lower relapse rates with twin transplantation. This may be related to the lack of tumor cells in the graft or graft-versus-myeloma effect without GVHD. The results of syngeneic transplantation are also superior to those of allogeneic SCT because of a low transplant-related mortality rate and the absence of clinical GVHD. These observations were based on the reports published from two large transplant registries, the Center for International Bone Marrow Transplant Research and European Bone Marrow Transplantation Registry.

Maintenance

Maintenance therapy is the use of ongoing low-intensity chemotherapy to eliminate or suppress the minimal residual tumor clone over a prolonged period of time. Maintenance therapy is administered when the disease is in remission, either undetectable or at a low level. The purpose of maintenance therapy is to prolong remission duration and thereby life expectancy. Maintenance therapy improves the quality of response, supporting the notion that an additional antitumor response during the maintenance phase will be beneficial. Immunomodulatory molecules are well suited for maintenance therapy because they can be administered orally at low doses for a prolonged period of time.[37]

The first two randomized trials published on thalidomide maintenance after autotransplant showed an improvement in PFS and OS. The total therapy II trial randomized patients to thalidomide induction and a maintenance arm versus a no-thalidomide arm; this study showed improvement in PFS and a delayed improvement in OS after 8 years of follow-up. In the HOVON 50 trial, patients were similarly randomized to thalidomide induction followed by thalidomide maintenance after transplant or VAD induction followed by interferon maintenance. This trial also showed improvement in PFS and OS for patients in the thalidomide arm. A meta-analysis of published results to date indicates a significant reduction of the risk for progression with thalidomide maintenance therapy. Outcome did not differ between trials that used thalidomide during the maintenance phase only and those that used thalidomide, both for induction and maintenance treatment. The MRC IX trial had an intensive therapy arm (SCT) and nonintensive arm (no stem cell transplant); after the patients had completed the intensive or nonintensive treatment arm, they were randomized to receive thalidomide maintenance or no maintenance. There was improvement in PFS but no improvement in OS when comparing the two groups. Results of major randomized studies evaluating maintenance therapy are summarized in Table 85-21.

Three large randomized trials have explored the role of lenalidomide as maintenance therapy. There were two studies of maintenance therapy after autologous SCT comparing lenalidomide vs. placebo (CALGB and IFM). A third trial compared 9 cycles of MP alone, MP with lenalidomide and MP with lenalidomide followed my lenalidomide. maintenance. All three studies showed improvement in PFS by 18 months; only the CALGB study showed improvement in OS. There appears to be a slightly increased risk of occurrence of a second malignancy when lenalidomide is administered along with melphalan or immediately after HDT with melphalan. Lenalidomide therapy is also unable to alter the poor prognosis attributed by adverse cytogenetics or FISH results.

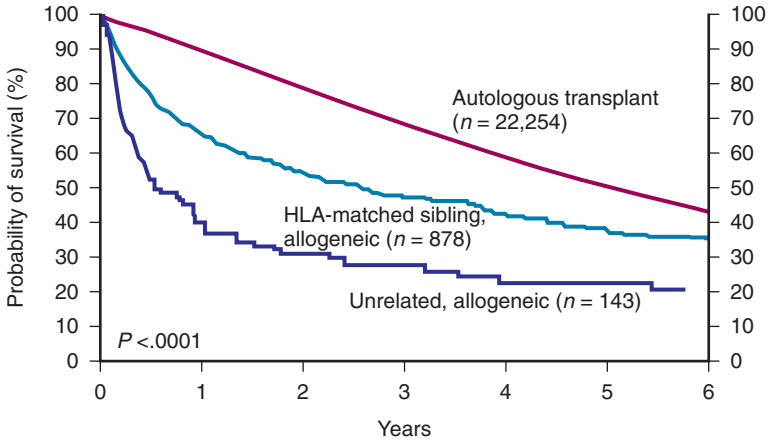

Figure 85-18 CENTER FOR INTERNATIONAL BONE MARROW TRANSPLANT RESEARCH ANALYSIS OF ALL TRANSPLANTS IN MYELOMA. Among 23,197 patients who received an autotransplant for multiple myeloma (MM) between 2000 and 2009, the 3-year probability of survival rate was 70% ± 1%. Allogeneic stem cell transplantation for MM is reserved for patients with high-risk disease, and the majority are performed after an autologous hematopoietic cell transplantation (HCT) with reduced-intensity or nonmyeloablative conditioning regimens. Among the 979 patients who received an allogeneic HCT from 2000 to 2009, the 3-year probabilities of survival were 51% ± 2% for the 827 recipients of human leukocyte antigen (HLA)–matched sibling donor grafts and 26% ± 2% for the 470 recipients of unrelated donor grafts. *(From Pasquini MD, Wang Z: CIBMTR summary slides, 2010. Adapted from* http://www.cibmtr.org.*)*

Bortezomib has also been used in the maintenance setting. Generally, bortezomib maintenance has been restricted to clinical trials in which bortezomib was also used in the induction phase of the treatment. Bortezomib maintenance seemingly improved the outcome in patients with high-risk cytogenetics or FISH results. Bortezomib is given less frequently in the maintenance setting; different studies have used different schedules of administration.

Relapsed Disease

Relapse is defined as reappearance of signs and symptoms of the disease or signs of increasing disease or end-organ dysfunction that are believed to be related to the underlying myeloma.[38a] Patients presenting with symptomatic relapse require treatment intervention. Patients with rapidly rising paraprotein, doubling of the paraprotein within a short interval, also require treatment intervention. Patients with asymptomatic biochemical relapse do not require treatment intervention. Generally, a serum M spike greater than 1 g/dL, Bence-Jones proteinuria greater than 500 mg/day, or serum-free light-chain level greater than 200 mg/L would be a minimum requirement to consider intervention with systemic therapy. Occasionally, myeloma cells may become dedifferentiated or anaplastic and may produce only light-chain components (Bence Jones escape phenomenon) or no paraprotein at all. These patients generally tend to have a more aggressive clinical course. Development of compression fractures and fractures at a site of previous lytic lesion per se need not constitute progression of myeloma. Development of hypercalcemia, progressive anemia, and new or worsening kidney function would merit prompt treatment intervention.

Currently relapsed and refractory disease is defined as having failed three or more lines of prior therapy with previous exposure to all four classes of drugs (cytotoxic agents, immunomodulatory agents, proteasome inhibitors, and glucocorticoids) and progressing on the last line of therapy. These patients have life expectancy of less than 1 year.

There are several considerations in choosing the treatment for patients with relapsed myeloma.[38a] These include disease-related factors such as slow, indolent, or a single site of relapse or rapid and multiple sites of relapse. Patients with a single site of relapse may be amenable to radiation treatment. Special considerations need to be given for patients presenting with extramedullary soft tissue plasmacytomas, CNS relapses, or plasma cell leukemia. Disease presenting with elevated LDH, high β_2-microglobulin, deletions 17p and multiple copies of 1q generally have a poor prognosis. Patients presenting with advanced age, poor performance status, renal impairment, and poor hematologic reserve or concurrent myelodysplastic syndrome from prior therapy present a great challenge for management. The choice of treatment is also predicated on prior drug exposure, whether the relapse is on or off therapy, and ongoing toxicity from prior therapy.

Thalidomide

Thalidomide monotherapy was originally introduced for the treatment of advanced and refractory myeloma. In the initial phase 2 trial, thalidomide was administered at 200 mg/day with increments every 2 weeks up to 800 mg for 169 patients. A partial response or better was noted in 30% of patients with a 2-year EFS of 20% and OS of 48%. A phase 3 trial (OPTIMUM) compared dexamethasone with thalidomide monotherapy at daily doses of 100, 200, and 400 mg. The median times to progression were 6, 7, 8, and 9.1 months, respectively. The response rates and median survival rates were similar in all treatment groups. In a systematic review of 1629 patients with relapsed myeloma treated on 42 uncontrolled phase II trials with thalidomide, a partial response or better was noted in 30% with 1 year survival of 60%, as reported by Glasmacher et al.[38b] Thalidomide has been combined successfully with other conventional chemotherapy agents as well as proteasome inhibitors for improved response rates and better disease control. Thalidomide is especially useful when a patient presents with renal impairment and cytopenias. It is also useful for palliation when combined with oral cyclophosphamide and prednisone in patients with poor performance status.

Lenalidomide

In two large phase 3 randomized trials (MM 009 and MM 010) lenalidomide–dexamethasone was found to be superior to dexamethasone in patients with relapsed myeloma after one to three lines of prior therapy. Updated results with a median follow-up of 48 months showed an ORR of 61%, median time to progression of 13.4 months, duration of response of 16 months, and OS of 38 months. Patients who had more than one line of prior therapy had an ORR of 57%; time to progression was 10.6 months. A median PFS of 9.5 months and OS of 31 months were reported. Patients with moderate or severe renal impairment developed more severe thrombocytopenia, required more frequent dose modifications, and had inferior survival outcomes. Prior exposure to thalidomide did not preclude responses to lenalidomide; however, patients who had relapsed or progressed on thalidomide have a lower response rate (<50%) and a shorter time to progression (7 months). Lenalidomide can be easily combined with conventional chemotherapy as well as bortezomib. Combination therapy results in a higher response rate and better disease control.

Bortezomib

In a large phase 2 trial (SUMMIT) conducted in relapsed and refractory MM, bortezomib monotherapy had an impressive ORR of 28%,

Table 85-21 Randomized Studies Comparing Maintenance Therapy in Myeloma

Reference	Regimen	PFS (median mo)	OS (median mo)
Spencer[110]	Control vs. thalidomide/prednisone	3-yr 23 vs. 42 (P <.001)	3-yr 75 vs. 86 (P = .004)

including 10% complete or near-complete remissions. The median time to progression was 7 months, the duration of response was 12.7 months, and the median survival time was 17 months. Among patients with relapsed myeloma after one to three lines of prior therapy, bortezomib monotherapy had an ORR of 43%, a median time to progression of 6.2 months, a duration of response of 8 months, and a median survival time of 30 months. Bortezomib monotherapy is less effective in patients who have received more than one line of prior therapy. Bortezomib is also synergistic when used in combination with other drugs, including alkylating agents, anthracyclines, immunomodulatory drugs, and dexamethasone. These combinations generally produce higher ORRs in the range of 50% to 80%, with an increasing duration of response and OS. Bortezomib plus pegylated liposomal doxorubicin has been shown to be superior to monotherapy in a large, randomized trial with an improved time to progression (9.3 vs. 6.5 months) and OS. Bortezomib has also been recently used as subcutaneous injection and in a randomized comparison with intravenous administration had identical 42% response in both subcutaneous administration had improved safety profile with reduced incidence of peripheral neuropathy (38% vs. 53%; $P = .044$ of any grade and 6% vs. 16%; $P = .026$ grade 3 or worse).[39]

Carfilzomib

Carfizomib is a tetrapeptide epoxyketone that selectively and irreversibly inhibits the 20S proteasome at the same chymotrypsin-like enzymatic site as bortezomib. In preclinical models it has been shown to overcome bortezomib-resistance. Carfilzomib has been shown to be effective in patients with relapsed multiple myeloma, who had received at least 2 lines of therapy, including bortezomib and an immunomodulatory agent (thalidomide or lenalidomide). In a single arm, multicenter clinical trial enrolling 266 patients with relapsed myeloma, Carfilzomib as a single agent induced an overall response rate of 23%, consisting of 1 complete response, 13 very good partial responses and 47 partial responses. The median response duration was 7.8 months and overall survival was 15.6 months. Most common adverse events included fatigue, anemia, nausea, and thrombocytopenia, dyspnea, diarrhea, and pyrexia. Neuropathy was uncommon (12.4%) and mild (grade 1 or 2). The drug has been combined successfully with other antimyeloma agents such as lenalidomide and dexamethasone (CRD) with greater efficacy, both in relapsed setting as well as in newly diagnosed multiple myeloma. Currently there is an ongoing phase III clinical trial comparing lenalidomide and weekly dexamethasone (Rd) to lenalidomide, weekly dexamethasone plus Carfilzomib. Carfilzomib has been recently approved for the treatment of patients with multiple myeloma who have received at least two prior therapies, including bortezomib and an immunomodulatory agent, and have demonstrated disease progression on or within 60 days of the completion of the last therapy.

Lenalidomide, Bortezomib, and Dexamethasone

As in newly diagnosed patients, a combination of lenalidomide, bortezomib, and dexamethasone[29] is able to achieve responses in relapsed patients as well as patients refractory to either or both agents separately. In a phase I/II study, 38 patients received lenalidomide with or without dexamethasone. Among 36 evaluable patients, 61% achieved a minimal response or better. Among 18 patients who had dexamethasone added, 83% achieved stable disease or better with a median OS time of 37 months. This has established RVD as one of the salvage regimens in relapsed myeloma if this combination has not been used when the patient was newly diagnosed.

Newer Agents

A number of novel agents have been validated using both in vitro and in vivo models.[40] These models have been developed to characterize MM cell–BMSC interactions, as well as signaling pathways controlling growth, survival, drug resistance, or migration within the BM milieu. These studies identified that MM cell growth is mediated via the ERK/MAPK pathway, survival via JAK/STAT signaling, drug resistance via PI3K/Akt signaling, and migration via PKC-dependent signaling cascades. These systems have been used to identify potential novel therapeutic targets and to validate novel targeted therapies (Table 85-22). The immunomodulatory agent pomalidomide and the proteasome inhibitor carfilzomib are two promising drugs. In a phase I/II study, pomalidomide with dexamethasone was shown to have an ORR 34% and minor response or better in 45% of patients. Similar responses were observed in patients who were refractory to both bortezomib and lenalidomide. Other representative novel agents include the histone deacetylase (HDAC) inhibitors vorinostat and panabinostat. A recent phase III study evaluating vorinostat with bortezomib versus placebo and bortezomib has confirmed significant improvement in response with the combination (ORR, 56% vs. 41%; $P < .0001$ and PFS, 7.65 vs. 6.83; $P = .01$).

A similar study evaluating combination of panabinostat with bortezomib versus bortezomib is ongoing. In a phase II study in relapsed or refractory patients, the anti–CS-1 mAb (monoclonal antibody) elotuzumab was evaluated in combination with lenalidomide and dexamethasone and was shown to lead to an 82% ORR; a phase III study evaluating this combination with lenalidomide and dexamethasone is ongoing. CS-1 is a cell surface glycoprotein highly expressed by MM cells irrespective of cytogenetic abnormalities or response to various treatment options. Similarly, a phase I/II study combining perifosine (an Akt inhibitor) with bortezomib with or without dexamethasone has shown a 41% ORR, including a 32% response in bortezomib-refractory patients; a phase III study evaluating this combination with bortezomib alone is ongoing. Other promising targets and agents and the stages of their clinical development are listed in Table 85-22.

The optimal treatment of a relapsed patient requires ensuring that the patient's relapse requires intervention. Approach to therapy is dictated by whether the patient had a transplant or is a transplant candidate, and the selection of possible drug depends on prior therapy received. Additional selection criteria should consider patient characteristics such as age, risk factors, existing comorbidities such as renal failure, and previous toxicities such as neuropathy, and finally patient convenience. Improving complete response rates is a key goal of current trials in relapsed patients as well.

Bisphosphonates

The aminobisphosphonates pamidronate and zoledronate have been investigated in patients with myeloma and bone disease and have been shown to reduce skeletal complications and bone pain. A number of older randomized studies looked at their efficacy in patients with existing bone lesions and evaluated the development of new skeletal-related events. In this regards, pamidronate 90 mg and zoledronic acid 4 mg are equipotent in reducing bone-related problems in MM; the infusion time for zoledronic acid is 15 minutes compared with 1 to 2 hours for pamidronate. A recent large study, MRC IX, evaluated the efficacy of zoledronic acid in a randomized comparison with clodronate. This study in 1960 patients confirmed the efficacy and superiority of zoledronic acid in preventing new SREs in patients both with and without existing bone lesions (Table 85-23) and provided evidence that its continued use beyond 2 years was beneficial[41]; importantly, the study also suggested that zoledronic acid compared with clodronate improves an OS advantage providing for the first time some evidence of its antimyeloma activity (Fig. 85-19).[42] A similar survival advantage has also been reported with pamidronate (21 vs. 14 months; $P = .041$) in patients receiving salvage chemotherapy and pamidronate versus chemotherapy alone. Pamidronate administration alone has also been shown to produce responses or delays in disease progression in occasional patients. The bisphosphonate has multiple actions, including suppression of

Table 85-22 Novel Target in Myeloma, Agents, and Stage of Ongoing Clinical Trials

D** and **E,** Kaplan-Meier analyses of overall survival (OS) with ZOL versus CLO in patients with **(D)** or without **(E)** bone disease or other SRE at baseline. The benefit appears to be predominantly in those with prior SREs. *CI,* Confidence interval; *HR,* hazard ratio. *(Adapted from Morgan GJ, Child JA, Gregory WM, et al: Effects of zoledronic acid versus clodronic acid on skeletal morbidity in patients with newly diagnosed multiple myeloma (MRC Myeloma IX): Secondary outcomes from a randomised controlled trial. 12:743, 2011 and Morgan, GJ, Davies FE, Gregory WM, et al: Effects of induction and maintenance plus long-term bisphosphonates on bone disease in patients with multiple myeloma: The Medical Research Council Myeloma IX Trial.* Blood *119:5374, 2012.)*

osteoclast number and function, inhibition of IL-6 production by stromal cells, inhibition of farnesyl and geranyl–geranyl transferase activity, and immune effects via γ/δ T cells.

Two potential side effects of bisphosphonates—effects on renal function and development of osteonecrosis of the jaw (ONJ)—have limited their very long-term use in the recent past. ONJ is observed in patients with dental infection or procedures after its longer term use. Its frequency has been between 3% and 5%. In one study, 11 of 292 patients (3.8%) with MM developed ONJ. Patients receiving bisphosphonates require a thorough dental checkup before starting therapy and should have frequent dental follow-ups with careful and conservative use of dental procedures. With these precautions, the frequency of ONJ has been reduced. Similarly, measurement of renal function before each bisphosphonate dose and adjustment of dose based on renal function also make use of bisphosphonates safer. A slower administration of bisphosphonates prevents or protects against

the development of renal dysfunction. Most recently, recommendations for the duration of bisphosphonate use has been for 2 years with reduction in frequency after that if patients enjoy a good remission. However, in light of the recent MRC-IX study, this recommendation will need revision with suggestion of possible long-term use. Additional bone-directed targets and agents are in development that have the ability to further inhibit osteoclast function (denosumab) and to improve osteoblast activity with bone anabolic effects (DKK-1–BHQ-880 and activin A–ACE-011). These agents are currently under clinical investigation in myeloma.

FUTURE DIRECTIONS

Significant advances have occurred in our understanding of pathobiology of MM that have translated into development of novel therapeutics. Predictive in vitro and in vivo models have been developed to study growth and survival characteristics of MM cells in the context of the BM microenvironment, but more importantly, to preclinically evaluate the efficacy of novel targeted agents. Similarly, there has been an explosion of genomic data covering various genomic correlates, including expression profile, CNA, alternate splicing, miRNA and now whole-genome sequencing and mutational analysis of both expressed genes as well as noncoding regions. Evolving understanding of the epigenomic alterations that affect cell growth, survival, and development of drug resistance is providing clues for novel interventions. For example, MM cell proliferation is now considered to be dependent on the bromodomain and extra-terminal (BET) domain family of bromodomain-containing proteins (BRD2, BRD3, and BRD4), which are novel therapeutic targets. These model systems and our improved understanding have led to new drug developments with seven new agents in advanced phase III studies in myeloma and more than 20 other novel agents in phase I or II studies. The genomic information is being integrated to develop more accurate risk stratification model and to develop personalized medicine to optimize response while avoiding the toxicity of agents that may not be effective in a given patient. Finally, because of these advances, the median survival time of MM patients has increased from 3 years to more than 7 to 8 years, and in a number of individuals, it becomes a chronic disease with curative outcome predicted in a proportion of patients in the near future.

CHAPTER 86

WALDENSTRÖM MACROGLOBULINEMIA AND LYMPHOPLASMACYTIC LYMPHOMA

Steven P. Treon and Giampaolo Merlini

Waldenström macroglobulinemia (WM) is a distinct clinicopathologic entity resulting from the accumulation, predominantly in the bone marrow (BM), of clonally related lymphocytes, lymphoplasmacytic cells, and plasma cells that secrete a monoclonal immunoglobulin M (IgM) protein (Fig. 86-1).[1] This condition is considered to correspond to the lymphoplasmacytic lymphoma (LPL) as defined by the World Health Organization lymphoma classification system.[2] Most cases of LPL are WM, with fewer than 5% of cases made up of IgA, IgG, and nonsecreting LPL.

EPIDEMIOLOGY

Waldenström macroglobulinemia is an uncommon disease, with a reported age-adjusted incidence rate of 3.4 per million among males and 1.7 per million among females in the United States and a geometrical increase with age.[3] The incidence rate for WM is higher among whites, with African descendants representing only 5% of all patients. The incidence of WM may be higher among individuals of Ashkenazi Jewish descent.[4] Genetic factors appear to be important to the pathogenesis of WM. A common predisposition for WM with other malignancies has been raised,[4,5] with numerous reports of familial clustering of individuals with WM alone and with other B-cell lymphoproliferative diseases.[6-10] In a large single-center experience, 26% of 924 consecutive patients with WM had a first- or second-degree relative with either WM or another B-cell disorder.[5] Frequent familial association with other immunologic disorders in healthy relatives, including hypogammaglobulinemia and hypergammaglobulinemia (particularly polyclonal IgM), autoantibody (particularly to thyroid) production, and manifestation of hyperresponsive B cells have also been reported.[10,11] Increased expression of the *bcl-2* gene with enhanced B-cell survival may underlie the increased immunoglobulin synthesis in familial WM.[10] The role of environmental factors in WM remains to be clarified, but chronic antigenic stimulation from infections, certain drugs, and Agent Orange exposures remain suspect. An etiologic role for hepatitis C virus (HCV) infection has been suggested, but in one study, no association could be established using both serologic and molecular diagnostic studies for HCV infection in 100 consecutive WM patients.[12,13]

PATHOBIOLOGY

Cytogenic Abnormalities

Chromosome 6q deletions encompassing 6q21-25 have been observed in up to half of WM patients and at a comparable frequency among patients with and without a familial history.[7,14-16] The presence of 6q deletions has been suggested to distinguish patients with WM from those with IgM monoclonal gammopathy of unknown significance (MGUS) and to have potential prognostic significance, including impacting on progression-free survival (PFS) after treatment, although others have reported no prognostic significance to the presence of 6q deletions in WM.[14,16,17] Other abnormalities observed by cytogenetic or fluorescent in situ hybridization (FISH) analyses include deletions in 13q14, TP53 and ATM, trisomy 4, 12, and 18.[17,18] IgH rearrangements are uncommon in WM and may be helpful in distinguishing cases of WM from IgM myeloma in which IgH switch region rearrangements are a prominent feature.[19]

Mutation in MYD88

A highly recurrent somatic mutation (MYD88 L265P) has recently been identified in WM patients by paired tumor and normal whole-genome sequencing and subsequent confirmation by Sanger sequencing.[20] MYD88 L265P was expressed in tumor cells from 91% of LPL cases, which included patients with IgM- (WM) and IgG-secreting LPL. By comparison, MYD88 L265P was absent in myeloma samples, including IgM myeloma, and was expressed in a small subset (6.5%) of marginal zone lymphoma (MZL) patients, who surprisingly had many WM-related features. The expression of MYD88 L265P occurs in familial and sporadic WM patients at the same frequency. These findings appear to indicate that acquisition of MYD88 L265P is a common transforming event for WM regardless of familial predisposition. Importantly, whereas knock-down of MYD88 decreased survival of MYD88 L265P expressing WM cells, survival was more enhanced by knock-in of MYD88 L265P versus wild-type MYD88. The discovery of a mutation in MYD88 is of significance given its role as an adaptor molecule in Toll-like receptor (TLR) and interleukin-1 receptor (IL-1R) signaling.[21] All TLRs except for TLR3 use MYD88 to facilitate their intracellular signaling. After TLR or IL-1R stimulation, MYD88 is recruited to the activated receptor complex as a homodimer, which then complexes with IRAK4 and activates IRAK1 and IRAK2.[22-24] Tumor necrosis factor receptor associated factor 6 is then activated by IRAK1, leading to nuclear factor kappa-B (NFκB) activation via IκBα phosphorylation.[25] Exposure to inhibitors of MYD88 pathway leads to decreased IRAK1 and IκBα phosphorylation, as well as survival of MYD88 L265P expressing WM cells. These observations are of particular relevance to WM because NFκB signaling is important for WM growth and survival.[26]

Nature of the Clonal Cell

The WM BM B-cell clone shows intraclonal differentiation from small lymphocytes with large focal deposits of surface immunoglobulins to lymphoplasmacytic cells to mature plasma cells that contain intracytoplasmic immunoglobulins.[27] Clonal B cells are detectable among blood B lymphocytes, and their number increases in patients who fail to respond to therapy or who progress.[28] These clonal blood cells possess the peculiar capacity to differentiate spontaneously in vitro culture to plasma cells. This occurs through an IL-6–dependent process in IgM MGUS and mostly an IL-6–independent process in WM patients.[29] All of these cells express the monoclonal IgM present in the blood, and a variable percentage of them also express surface IgD. The characteristic immunophenotypic profile of the lymphoplasmacytic cells in WM includes the expression of the pan B-cell

markers CD19, CD20, CD22, CD79, and FMC7.2.[30-32] Expression of CD5, CD10, and CD23 may be found in 10% to 20% of cases and does not exclude the diagnosis of WM.[33]

The phenotype of lymphoplasmacytic cells in WM cells suggests that the clone is a postgerminal center B cell. This phenotype is further strengthened by the results of the analysis of the nature (silent or amino acid replacing) and distribution (in framework or CDR regions) of somatic mutations in Ig heavy- and light-chain variable regions performed in patients with WM cells.[34,35] This analysis showed a high rate of replacement mutations compared with the closest germline genes, clustering in the CDR regions without intraclonal variation. Subsequent studies showed a strong preferential usage of VH3/JH4 gene families, no intraclonal variation, and no evidence for any isotype-switched transcripts.[36,37] These data indicate that WM may originate from an IgM^+ or IgM^+ IgD^+ memory B cell (or both). Normal IgM^+ memory B cells localize in BM, where they mature to IgM-secreting cells.[38]

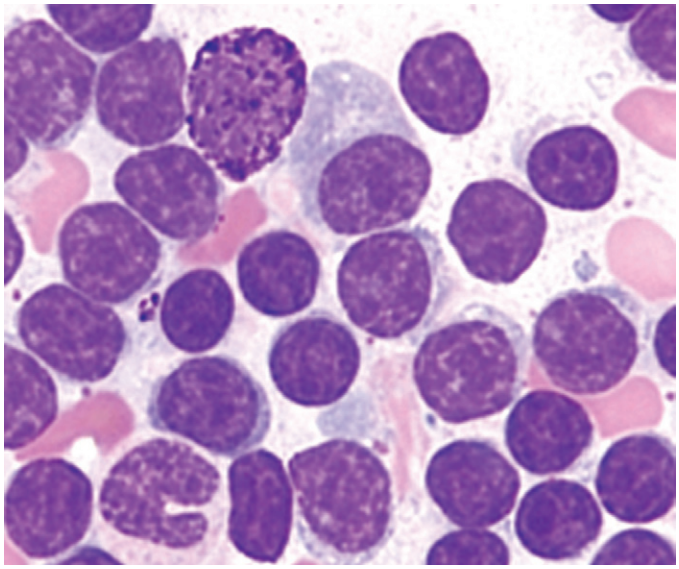

Figure 86-1 ASPIRATE FROM A PATIENT WITH WALDENSTRÖM MACROGLOBULINEMIA DEMONSTRATING EXCESS MATURE LYMPHOCYTES, LYMPHOPLASMACYTIC CELLS, AND PLASMA CELLS.

Bone Marrow Microenvironment

Increased numbers of mast cells are found in the BM of WM patients (Fig. 86-2), wherein they are usually admixed with tumor aggregates.[2,32,39] The role of mast cells in WM has been investigated in one study wherein coculture of primary autologous or mast cell lines with WM LPC resulted in dose-dependent WM cell proliferation or tumor colony formation, primarily through CD40 ligand (CD40L) signaling. Furthermore, WM cells through elaboration of soluble CD27 (sCD27) induced the upregulation of CD40L on mast cells derived from WM patients and mast cell lines, suggesting a microenvironmental support system[39,40] High levels of expression of CXCR4 and VLA-4 in WM cells have been observed.[41] In blocking experiment studies, CXCR4 was shown to support migration of WM cells, and VLA-4 contributed to adhesion of WM cells to BM stromal cells.

CLINICAL MANIFESTATIONS

The clinical and laboratory findings at time of diagnosis of WM in one large institutional study are presented in Table 86-1. Unlike most indolent lymphomas, splenomegaly and lymphadenopathy are prominent in only a minority of patients (≤15%). Purpura is frequently associated with cryoglobulinemia and more rarely with amyloid light-chain (AL) amyloidosis, but hemorrhagic manifestations and neuropathies are multifactorial (see below). The morbidity associated with WM is caused by the concurrence of two main components: tissue infiltration by neoplastic cells and, more importantly, the physicochemical and immunologic properties of the monoclonal IgM. As shown in Table 86-2, the monoclonal IgM can produce clinical manifestations through several different mechanisms related to its physicochemical properties, nonspecific interactions with other proteins, antibody activity, and tendency to deposit in tissues.[42-44]

MORBIDITY CAUSED BY THE EFFECTS OF IMMUNOGLOBULIN M

Hyperviscosity Syndrome

Increased serum IgM levels lead to blood hyperviscosity-related complications.[45] The mechanisms behind the marked increase in the

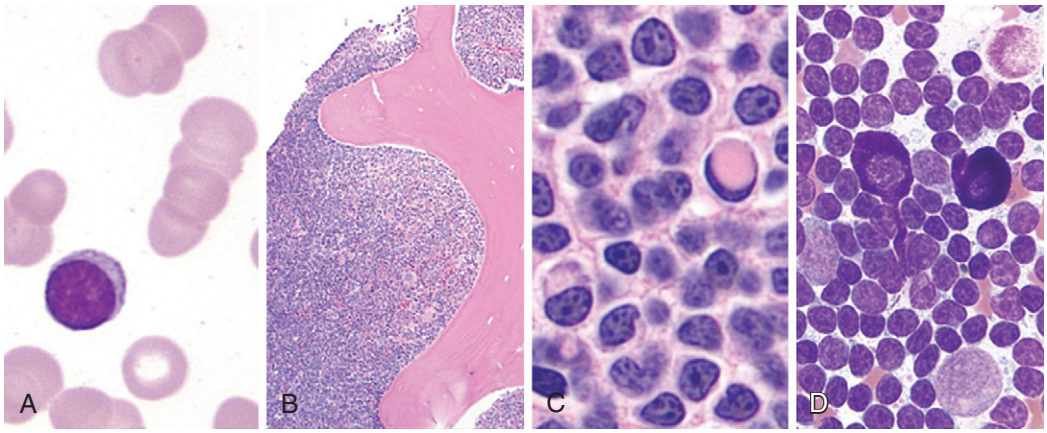

Figure 86-2 LYMPHOPLASMACYTIC LYMPHOMA CONSISTENT WITH WALDENSTRÖM MACROGLOBULINEMIA. The patient was a 78-year-old man who first presented with anemia. Serum electrophoresis demonstrated an immunoglobulin M (IgM) κ monoclonal protein, and quantitative immunoglobulins showed an IgM of 5130 mg/dL. His serum viscosity was elevated at 2.9 centipoise (cP). The peripheral blood smear showed circulating lymphoma cells with slight plasmacytic appearance **(A).** There was also marked rouleaux formation of the red blood cells. The bone core biopsy showed a paratrabecular and interstitial infiltrate of malignant lymphoid cells **(B),** which at higher power included many with intranuclear inclusions or Dutcher bodies (**C,** *center*). The aspirate **(D)** was packed with lymphoplasmacytic cells associated with increased mast cells *(upper left).* The phenotype was $CD19^+$, $CD20^+$, IgM/κ^+ with no CD5, CD10, or CD11c expression.

resistance to blood flow and the resulting impaired transit through the microcirculatory system are rather complex.[45-47] The main determinants are (1) a high concentration of monoclonal IgMs, which may form aggregates and may bind water through their carbohydrate component, and (2) their interaction with blood cells. Monoclonal IgMs increase red blood cell (RBC) aggregation (*rouleaux* formation) and RBC internal viscosity while also reducing deformability. The possible presence of cryoglobulins can contribute to increasing blood viscosity as well as to the tendency to induce erythrocyte aggregation. Serum viscosity is proportional to the IgM concentration up to 30 g/L and then increases sharply at higher levels. Plasma viscosity and hematocrit levels are directly regulated by the body. Increased plasma viscosity may also contribute to inappropriately low erythropoietin production, which is the major cause for anemia in these patients.[48] Clinical manifestations are related to circulatory disturbances that can be best appreciated by ophthalmologic examination, which shows distended and tortuous retinal veins, hemorrhages, and papilledema[49] (Fig. 86-3). Symptoms usually occur when the monoclonal IgM concentration exceeds 50 g/L or when serum viscosity is greater than 4.0 centipoises (cp), but there is a great individual variability, with some patients showing no evidence of hyperviscosity even at 10 cp.[45] The most common symptoms are oronasal bleeding, visual disturbances caused by retinal bleeding, and dizziness that may rarely lead to coma. Heart failure can be aggravated, particularly in elderly adults, owing to increased blood viscosity, expanded plasma volume, and anemia. Inappropriate transfusion can exacerbate hyperviscosity and may precipitate cardiac failure.

Table 86-1 Clinical and Laboratory Findings for 149 Consecutive Newly Diagnosed Patients With the Consensus Panel Diagnosis of Waldenström Macroglobulinemia Presenting to the Dana Farber Cancer Institute

	Median	Range	Institutional Normal Reference Range
Age (yr)	59	34-84	NA
Gender (male/female)	85/64		NA
BM involvement	30%	5%-95%	NA
Adenopathy	16%		NA
Splenomegaly	10%		NA
IgM (mg/dL)	2870	267-12,400	40-230
IgG (mg/dL)	587	47-2770	700-1600

Table 86-2 Physicochemical and Immunologic Properties of the Monoclonal IgM Protein in Waldenström Macroglobulinemia

Properties of IgM Monoclonal Protein	Diagnostic Condition	Clinical Manifestations
Pentameric structure	Hyperviscosity	Headaches, blurred vision, epistaxis, retinal hemorrhages, leg cramps, impaired mentation, intracranial hemorrhage
Precipitation on cooling	Cryoglobulinemia (type I)	Raynaud phenomenon, acrocyanosis, ulcers, purpura, cold urticaria
Autoantibody activity to MAG, GM1, sulfatide moieties on peripheral nerve sheaths	Peripheral neuropathies	Sensorimotor neuropathies, painful neuropathies, ataxic gait, bilateral foot drop
Autoantibody activity to IgG	Cryoglobulinemia (type II)	Purpura, arthralgias, renal failure, sensorimotor neuropathies
Autoantibody activity to RBC antigens	Cold agglutinins	Hemolytic anemia, Raynaud phenomenon, acrocyanosis, livedo reticularis
Tissue deposition as amorphous aggregates	Organ dysfunction	Skin: bullous skin disease, papules, Schnitzler syndrome GI: diarrhea, malabsorption, bleeding Kidney: proteinuria, renal failure (light-chain component)
Tissue deposition as amyloid fibrils (light-chain component most commonly)	Organ dysfunction	Fatigue, weight loss, edema, hepatomegaly, macroglossia, organ dysfunction of involved organs (heart, kidney, liver, peripheral sensory and autonomic nerves)

GI, Gastrointestinal; *GM1,* ganglioside M1; *Ig, immunoglobulin; MAG,* myelin-associated glycoprotein; *RBC,* red blood cell.

Figure 86-4 CRYOGLOBULINEMIA MANIFESTING WITH SEVERE ACROCYANOSIS IN A PATIENT WITH WALDENSTRÖM MACROGLOBULINEMIA BEFORE **(A)** AND AFTER **(B)** WARMING AND PLASMAPHERESIS.

Cryoglobulinemia

In up to 20% of WM patients, the monoclonal IgM can behave as a cryoglobulin (type I), but it is symptomatic in 5% or fewer of the cases.[50] Cryoprecipitation is mainly dependent on the concentration of monoclonal IgM; for this reason, plasmapheresis and plasma exchange are commonly effective in this condition. Symptoms result from impaired blood flow in small vessels and include Raynaud phenomenon, acrocyanosis, and necrosis of the regions most exposed to cold (e.g., the tip of the nose, ears, fingers, and toes [Fig. 86-4]; malleolar ulcers, purpura, and cold urticaria). Renal manifestations may occur but are infrequent.

Autoantibody Activity

Monoclonal IgM may exert its pathogenic effects through specific recognition of autologous antigens, the most notable being nerve constituents, immunoglobulin determinants, and RBC antigens.

Immunoglobulin M–Related Neuropathy

Peripheral neuropathy has been estimated to occur in 5% to 38% of WM patients.[51-55] The nerve damage is mediated by diverse pathogenetic mechanisms: IgM antibody activity toward nerve constituents causing demyelinating polyneuropathies; endoneurial granulofibrillar deposits of IgM without antibody activity associated with axonal polyneuropathy; occasionally by tubular deposits in the endoneurium associated with IgM cryoglobulin; and rarely by amyloid deposits or by neoplastic cell infiltration of nerve structures.[56] Half of the patients with IgM neuropathy have a distinctive clinical syndrome that is associated with antibodies against a minor 100-kDa glycoprotein component of nerve, myelin-associated glycoprotein (MAG). Anti-MAG antibodies are generally monoclonal IgMκ and usually also exhibit reactivity with other glycoproteins or glycolipids that share antigenic determinants with MAG.[57-59] The anti–MAG-related neuropathy is typically distal and symmetrical, affecting both motor and sensory functions; it is slowly progressive with a long period of stability.[52,60] Most patients present with sensory complaints (paresthesias, aching discomfort, dysesthesias, or lancinating pains), imbalance and gait ataxia owing to lack of proprioception, and leg muscle atrophy in the advanced stage. Patients with predominantly demyelinating sensory neuropathy in association with monoclonal IgM to gangliosides with disialosyl moieties, such as GD1b, GD3, GD2, GT1b, and GQ1b, have also been reported.[61,62] Anti-GD1b and anti-GQ1b antibodies were significantly associated with predominantly sensory ataxic neuropathy. These antiganglioside monoclonal IgMs present core clinical features of chronic ataxic neuropathy with variable presence of ophthalmoplegia or RBC cold agglutinating activity. The disialosyl epitope is also present on RBC glycophorins, thereby accounting for the RBC cold agglutinin activity of anti-Pr2 specificity.[63,64] Monoclonal IgM proteins that bind to gangliosides with a terminal trisaccharide moiety, including GM2 and GalNac-GD1A, are associated with chronic demyelinating neuropathy and severe sensory ataxia that is unresponsive to corticosteroids.[65] Antiganglioside IgM proteins may also cross-react with lipopolysaccharides of *Campylobacter jejuni,* an infection that is known to precipitate the Miller Fisher syndrome, a variant of the Guillain-Barré syndrome.[66] This finding indicates that molecular mimicry may play a role in this condition. Antisulfatide monoclonal IgM proteins associated with sensory or sensorimotor neuropathy have been detected in 5% of patients with IgM monoclonal gammopathy and neuropathy.[67] Motor neuron disease has been reported in patients with WM and monoclonal IgM with anti-GM1 and sulfoglucuronyl paragloboside activity.[68] POEMS (polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes) syndrome is rarely associated with WM.[69]

Cold Agglutinin Hemolytic Anemia

Monoclonal IgM may present with cold agglutinin activity; that is, it can recognize specific RBC antigens below physiological temperatures, producing a chronic hemolytic anemia. This disorder occurs in fewer than 10% of WM patients[70] and is associated with cold agglutinin titers greater than 1:1000 in most cases. The monoclonal component is usually an IgMκ and reacts most commonly with I/i antigens with complement fixation and activation.[71,72] Mild chronic hemolytic anemia can be exacerbated after cold exposure, but rarely does hemoglobin drop below 70 g/L. The hemolysis is usually extravascular (removal of C3b opsonized cells by the reticuloendothelial system, primarily in the liver) and rarely intravascular resulting from

complement destruction of the RBC membrane. The agglutination of RBCs in the cooler peripheral circulation also causes Raynaud syndrome, acrocyanosis, and livedo reticularis. Macroglobulins with the properties of both cryoglobulins and cold agglutinins with anti-Pr specificity have been reported. These properties may have as a common basis the immune binding of the sialic acid–containing carbohydrate present on RBC glycophorins and on Ig molecules. Several other macroglobulins with a variety of antibody activities toward autologous antigens (e.g., phospholipids, tissue and plasma proteins) and foreign ligands have also been reported.

Tissue Deposition

The monoclonal protein can be deposited in several tissues as amorphous aggregates. Linear deposition of monoclonal IgM along the skin basement membrane is associated with bullous skin disease.[73] Amorphous IgM deposits in the dermis determine the so-called IgM storage papules on the extensor surface of the extremities—macroglobulinemia cutis.[74] Deposition of monoclonal IgM in the lamina propria or submucosa of the intestine may be associated with diarrhea, malabsorption, and gastrointestinal bleeding.[75,76] It is well known that kidney involvement is less common and less severe in WM than in multiple myeloma, probably because the amount of light chain excreted in the urine is generally lower in WM than in myeloma and because of the absence of contributing factors, such as hypercalcemia, although cast nephropathy has also been described in WM.[77] On the other hand, the IgM macromolecule is more susceptible to being trapped in the glomerular loops where ultrafiltration presumably contributes to its precipitation, forming subendothelial deposits of aggregated IgM proteins that occlude the glomerular capillaries.[78] Mild and reversible proteinuria may result and most patients are asymptomatic. The deposition of monoclonal light chain as fibrillar amyloid deposits (AL amyloidosis) is uncommon in patients with WM.[79] Clinical expression and prognosis are similar to those of other AL patients with involvement of heart (44%), kidneys (32%), liver (14%), lungs (10%), peripheral or autonomic nerves (38%), and soft tissues (18%). However, the incidence of cardiac and pulmonary involvement is higher in patients with monoclonal IgM than with other immunoglobulin isotypes. The association of WM with reactive amyloidosis (AA) has been documented rarely.[80,81] Simultaneous occurrence of fibrillary glomerulopathy, characterized by glomerular deposits of wide noncongophilic fibrils and amyloid deposits, has been reported in WM.[82]

Manifestations Related to Tissue Infiltration by Neoplastic Cells

Tissue infiltration by neoplastic cells is rare and can involve various organs and tissues, from the BM (described later) to the liver, spleen, lymph nodes, and possibly the lungs, gastrointestinal tract, kidneys, skin, eyes, and central nervous system. Pulmonary involvement in the form of masses, nodules, diffuse infiltrate, or pleural effusions is relatively rare, since the overall incidence of pulmonary and pleural findings reported for WM is only 3% to 5%.[83-85] Cough is the most common presenting symptom followed by dyspnea and chest pain. Chest radiographic findings include parenchymal infiltrates, confluent masses, and effusions. Malabsorption, diarrhea, bleeding, or obstruction may indicate involvement of the gastrointestinal tract at the level of the stomach, duodenum, or small intestine.[86-89] In contrast to multiple myeloma, infiltration of the kidney interstitium with lymphoplasmacytoid cells has been reported in WM,[90] but renal or perirenal masses are common.[91] The skin can be the site of dense lymphoplasmacytic infiltrates, similar to that seen in the liver, spleen, and lymph nodes, forming cutaneous plaques and, rarely, nodules.[92] Chronic urticaria and IgM gammopathy are the two cardinal features of Schnitzler syndrome, which is not usually associated initially with clinical features of WM,[93] although evolution to WM is common. Thus close follow-up of these patients is warranted. Invasion of articular and periarticular structures by WM malignant cells is rarely reported.[94] The neoplastic cells can infiltrate the periorbital structures, lacrimal gland, and retro-orbital lymphoid tissues, resulting in ocular nerve palsies.[95,96] Direct infiltration of the central nervous system by monoclonal lymphoplasmacytic cells as infiltrates or as tumors constitutes the rarely observed Bing-Neel syndrome, which is characterized clinically by confusion, memory loss, disorientation, and motor dysfunction.[97]

LABORATORY MANIFESTATIONS

Hematological Abnormalities

Anemia is the most common finding in patients with symptomatic WM and is caused by a combination of factors, including a mild decrease in RBC survival, impaired erythropoiesis, hemolysis, moderate plasma volume expansion, and blood loss from the gastrointestinal tract. Blood smears are usually normocytic and normochromic, and rouleaux formation is often pronounced. Electronically measured mean corpuscular volume may be elevated spuriously owing to erythrocyte aggregation. In addition, the hemoglobin estimate can be inaccurate (i.e., falsely high) because of interaction between the monoclonal protein and the diluent used in some automated analyzers.[98] Leukocyte and platelet counts are usually within the reference range at presentation, although patients may occasionally present with severe thrombocytopenia. As reported earlier, monoclonal B-lymphocytes expressing surface IgM and late-differentiation B-cell markers are uncommonly detected in blood by flow cytometry. A raised erythrocyte sedimentation rate is almost constantly observed in WM and may be the first clue to the presence of the macroglobulin. The clotting abnormality detected most frequently is prolongation of thrombin time. AL amyloidosis should be suspected in all patients with nephrotic syndrome, cardiomyopathy, hepatomegaly, or peripheral neuropathy. Diagnosis requires the demonstration of green birefringence under polarized light of amyloid deposits stained with Congo red.

Biochemical Investigations

High-resolution electrophoresis combined with immunofixation of serum and urine is recommended for identification and characterization of the IgM monoclonal protein. The light chain of the monoclonal IgM is κ in 75% to 80% of patients. A few WM patients have more than one M component. The concentration of the serum monoclonal protein is very variable but in most cases lies within the range of 15 to 45 g/L. Densitometry should be adopted to determine IgM levels for serial evaluations because nephelometry is unreliable and shows large intralaboratory as well as interlaboratory variation. The presence of cold agglutinins or cryoglobulins may affect determination of IgM levels; therefore, testing for cold agglutinins and cryoglobulins should be performed at diagnosis. If present, subsequent serum samples should be analyzed under warm conditions for determination of serum monoclonal IgM level. Although Bence Jones proteinuria is frequently present, it exceeds 1 g/24 hours in only 3% of cases. Although IgM levels are elevated in WM patients, IgA and IgG levels are most often depressed and do not demonstrate recovery even after successful treatment, suggesting that patients with WM harbor a defect that prevents normal plasma cell development or Ig heavy chain rearrangements.[99,100]

Serum Viscosity

Because of its large size (almost 1,000,000 daltons), most IgM molecules are retained within the intravascular compartment and can exert an undue effect on serum viscosity. Therefore, serum viscosity should be measured if the patient has signs or symptoms of hyperviscosity syndrome. Funduscopy remains an excellent indicator of

clinically relevant hyperviscosity. Among the first clinical signs of hyperviscosity, the appearance of peripheral and midperipheral dot and blot–like hemorrhages in the retina is best appreciated with indirect ophthalmoscopy and scleral depression.[49] In more severe cases of hyperviscosity, dot-, blot-, and flame-shaped hemorrhages can appear in the macular area along with markedly dilated and tortuous veins with focal constrictions, resulting in "venous sausaging" as well as papilledema.

Bone Marrow Findings

The BM is always involved in WM. Central to the diagnosis of WM is the demonstration, by trephine biopsy, of *BM infiltration by a lymphoplasmacytic cell population* constituted by small lymphocytes with evidence of plasmacytoid and plasma cell differentiation (see Figs. 86-1 and 86-2). The pattern of BM infiltration may be diffuse, interstitial, or nodular, showing usually an intertrabecular pattern of infiltration. A solely paratrabecular pattern of infiltration is unusual and should raise the possibility of follicular lymphoma.[1] The BM infiltration should routinely be confirmed by *immunophenotypic studies* (flow cytometry or immunohistochemistry) showing the following profile: $sIgM^+CD19^+CD20^+CD22^+CD79^+$.[30-32] Up to 20% of cases may express CD5, CD10, or CD23.[33] In these cases, care should be taken to satisfactorily exclude chronic lymphocytic leukemia and mantle cell lymphoma.[1] "Intranuclear" periodic acid–Schiff–positive inclusions (Dutcher-Fahey bodies)[101] consisting of IgM deposits in the perinuclear space and sometimes in intranuclear vacuoles may be seen occasionally in lymphoid cells in WM. An increased number of mast cells, usually in association with the lymphoid aggregates, is commonly found in WM, and their presence may help in differentiating WM from other B-cell lymphomas.[1,2]

Other Investigations

Magnetic resonance imaging (MRI) of the spine in conjunction with computed tomography (CT) of the abdomen and pelvis is useful in evaluating the disease status in WM.[102] BM involvement can be documented by MRI studies of the spine in more than 90% of patients, and CT of the abdomen and pelvis demonstrated enlarged nodes in 43% of WM patients.[102] Lymph node biopsy may show preserved architecture or replacement by infiltration of neoplastic cells with lymphoplasmacytoid, lymphoplasmacytic, or polymorphous cytologic patterns. The residual disease after high-dose chemotherapy with allogeneic or autologous stem cell rescue can be monitored by polymerase chain reaction–based methods using primers specific for the monoclonal Ig variable regions.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of WM includes other IgM-secreting B-cell disorders, including other B-cell lymphoma subtypes and multiple myeloma. MZL is the most common disease entity with which WM is often confused because of many overlapping clinicopathologic features, including morphologic, immunophenotypic, and cytogenetic features. A recent study found that a mutation in MYD88 (L265P) could be used to differentiate WM wherein it was expressed in over 90% of patients from MZL. The presence of translocations at chromosome 14 involving the immunoglobulin heavy-chain locus is commonly encountered in IgM myeloma, typically t(11;14), although it is absent in WM.[19]

Prognosis

Waldenström macroglobulinemia typically presents as an indolent disease, although considerable variability in prognosis can be seen. The median survival time reported in several large series has ranged from 5 to 10 years,[103-109] but in a recent study of 436 consecutive patients with WM, the median overall survival from time of diagnosis was in excess of 10 years.[110] Age is consistently an important prognostic factor (>60-70 years),[103,104,106,109] but it is often impacted by unrelated morbidities. Anemia, which can be multifactorial, is an adverse prognostic factor in WM, with hemoglobin levels of less than 9 to 12 g/dL associated with decreased survival in several series.[103-105,109] Cytopenias have also been regularly identified as a significant predictor of survival. The number of cytopenias in a given patient may predict survival.[104] Serum albumin levels have correlated with survival in WM patients in certain but not all studies using multivariate analyses.[104,107] High serum β-2 microglobulin (>3-3.5 g/dL) levels,[105,107,109] high serum IgM M protein (>7 g/dL),[109] low serum IgM M protein (<4 g/dL),[107] the presence of cryoglobulins,[103] and the presence of a familial disease background[110] have also been reported to confer adverse outcomes. The presence of 6q deletion as an adverse marker remains controversial.[14,16] A few prognostic scoring systems have been proposed (Table 86-3). Although the use of prognostic markers or scoring systems to make therapeutic decisions remains to be clarified,[106] patients with familial disease predisposition show better outcomes after bortezomib-based therapy.[110]

Therapy

As part of the International Workshops on WM, consensus panels developed guidelines for uniform response criteria in WM.[111,112] The category of minor response was adopted at the Third International Workshop of WM, given that clinically meaningful responses were observed with newer biological agents, and is based on 25% or greater to less than 50% decrease in serum IgM level, which is used as a surrogate marker of disease in WM. At the Sixth International Workshop on WM, the categorical response of very good partial response (VGPR) (i.e., 90% reduction in IgM levels) was adopted given reports of improved clinical outcome associated with VGPR or better response achievement.[113-116] In distinction, the term *major response* is used to denote a response of 50% or greater in serum IgM levels and includes partial or better responses.[112] Response categories and criteria for progressive disease in WM based on consensus recommendations are summarized in Table 86-4.

An important concern with the use of IgM as a surrogate marker of disease is that it can fluctuate independent of the extent of tumor cell killing, particularly with biologically targeted agents such as rituximab, bortezomib, or everolimus.[117-122] Rituximab induces a spike or flare in serum IgM levels that can occur when used as monotherapy and in combination with other agents, including cyclophosphamide, nucleoside analogues, thalidomide, and lenalidomide, and can last for several weeks to months.[117,119,123-126] Bortezomib and everolimus can suppress IgM levels independent of tumor cell killing in certain patients.[120,121,126] Moreover, Varghese et al[127] showed that in patients treated with selective B-cell depleting agents such as rituximab and alemtuzumab, residual IgM producing plasma cells are spared and continue to persist, thus potentially skewing the relative response and assessment to treatment. Therefore, in circumstances in which the serum IgM levels appear out of context with the clinical progress of the patient, a BM biopsy should be considered to clarify the patient's underlying disease burden. Soluble CD27 may serve as an alternative surrogate marker in WM and remains a faithful marker of disease in patients experiencing a rituximab-related IgM flare, as well as plasmapheresis.[40,128]

TREATMENT INDICATIONS

Consensus guidelines on indications for treatment initiation were formulated as part of the Second International Workshop on Waldenström's Macroglobulinemia.[106] Initiation of therapy should not be based on the IgM levels since this may not correlate with either disease burden or symptomatic status.[129,130] Initiation of therapy is appropriate for patients with constitutional symptoms, such as

Table 86-3 Prognostic Scoring Systems in Waldenström Macroglobulinemia

Table 86-4 Summary of Updated Response Criteria Adopted at the Sixth International Workshop on Waldenström Macroglobulinemia

Criterion	Abbreviation	Description
Complete response	CR	IgM in normal range and disappearance of monoclonal protein by immunofixation, no histologic evidence of BM involvement, and resolution of any adenopathy or organomegaly (if present at baseline) along with no signs or symptoms attributable to WM; reconfirmation of the CR status is required by repeat immunofixation studies
Very good partial response	VGPR	A ≥90% reduction of serum IgM and resolution in adenopathy or organomegaly (if present at baseline) on physical examination or on CT scan; no new symptoms or signs of active disease
Partial response	PR	A ≥50% reduction of serum IgM and decrease in adenopathy or organomegaly (if present at baseline) on physical examination or on CT scan; no new symptoms or signs of active disease
Minor response	MR	A ≥25% but <50% reduction of serum IgM; no new symptoms or signs of active disease
Stable disease	SD	A <25% reduction and <25% increase of serum IgM without progression of adenopathy or organomegaly, cytopenias, or clinically significant symptoms caused by disease or signs of WM
Progressive disease	PD	A ≥25% increase in serum IgM by protein confirmed by a second measurement or progression of clinically significant findings caused by disease (i.e., anemia, thrombocytopenia, leukopenia, bulky adenopathy or organomegaly) or symptoms (unexplained recurrent fever ≥38.4°C, drenching night sweats, ≥10% body weight loss, hyperviscosity, neuropathy, symptomatic cryoglobulinemia, or amyloidosis) attributable to WM

recurrent fever, night sweats, fatigue caused by anemia, or weight loss. The presence of progressive, symptomatic lymphadenopathy or splenomegaly provides additional reasons to begin therapy. The presence of anemia with a hemoglobin value of 10 g/dL or less or a platelet count 100 × 10^9/L or less on this basis of disease is also a reasonable indication for treatment initiation. Certain complications of WM, such as hyperviscosity syndrome, symptomatic sensorimotor peripheral neuropathy, systemic amyloidosis, renal insufficiency, or symptomatic cryoglobulinemia, are also indications for therapy.

TREATMENT OPTIONS

A precise therapeutic algorithm for therapy of WM remains to be defined given the paucity of randomized clinical trials. Active agents include alkylating agents (chlorambucil, cyclophosphamide), nucleoside analogues (cladribine, fludarabine), monoclonal antibodies (rituximab, ofatumumab, alemtuzumab), bortezomib, thalidomide, everolimus, and bendamustine.[129,130] Combination therapy, particularly with rituximab, has been associated with improved clinical

outcomes. Individual patient considerations, including the presence of cytopenias, need for more rapid disease control, age, and candidacy for autologous transplant therapy, should be taken into account in making the choice for frontline therapy. For patients who are candidates for autologous transplant therapy, exposure to continuous chlorambucil or nucleoside analogue therapy should be limited given the potential for stem cell damage associated with the use of these drugs. The use of nucleoside analogues may also increase the risk for histologic transformation to diffuse large B-cell lymphoma as well as myelodysplasia and acute myeloid leukemia (AML).[131]

Chlorambucil

Oral alkylating drugs, alone and in combination therapy with steroids, have been extensively evaluated as frontline treatment of WM. The greatest experience with oral alkylating agent therapy has been with chlorambucil, which has been administered on both a continuous (i.e., daily dose schedule) as well as an intermittent schedule. Patients receiving chlorambucil on a continuous schedule typically receive 0.1 mg/kg/day, but with the intermittent schedule, patients will typically receive 0.3 mg/kg for 7 days every 6 weeks. In a prospective randomized study, Kyle et al[132] reported no significant difference in the overall response rates between these schedules, although the median response duration was greater for patients receiving intermittent versus continuous chlorambucil (46 versus 26 months). Despite the favorable median response duration favoring the use of the intermittent treatment schedule, no difference in the median overall survival was observed. Moreover, an increased incidence of developing myelodysplasia and AML with the intermittent (three of 22 patients) versus the continuous (0 of 24 patients) treatment schedule prompted the authors of this study to express preference for use of continuous chlorambucil dosing. The use of steroids in combination with alkylating agent therapy has also been explored. Dimopoulos and Alexanian[133] evaluated chlorambucil (8 mg/m^2) along with prednisone (40 mg/m^2) given orally for 10 days, every 6 weeks, and reported a major response (i.e., reduction of IgM by greater than 50%) in 72% of patients. Non–chlorambucil-based alkylator regimens using melphalan and cyclophosphamide in combination with steroids have also been examined by Petrucci et al[134] and Case et al[135] producing slightly higher overall response rates and response durations, although the benefit of these more complex regimens over chlorambucil remains to be demonstrated. Facon et al[136] have evaluated parameters predicting for response to alkylator therapy. Their studies in patients receiving single-agent chlorambucil demonstrated that age older than 60 years, male sex, symptomatic status, and cytopenias (but, interestingly, not high tumor burden and serum IgM levels) were associated with poor response to alkylator therapy. Additional factors to be taken into account in considering alkylator therapy for patients with WM include necessity for more rapid disease control given the slow nature of response to alkylator therapy, as well as consideration for preserving stem cells in patients who are candidates for autologous transplant therapy.

Nucleoside Analogues

Both cladribine and fludarabine have been extensively evaluated in untreated as well as previously treated WM patients. Cladribine administered as a single agent by continuous intravenous infusion over 2 hours daily infusion or by subcutaneous injections for 5 to 7 days has resulted in major responses in 40% to 90% of patients who received these drugs as primary therapy, but in the salvage setting, response rates have ranged from 38% to 54%.[129-143] Median time for achievement of a response after cladribine ranged from 1.2 to 5 months. The overall response rate with daily infusional fludarabine therapy administered mainly on a 5-day schedule in previously untreated and treated WM patients has ranged from 38% to 100% and 30% to 40%, respectively,[105,144-150] which is similar to the response rates reported with cladribine. The median time to achievement of response for fludarabine was also similar to that reported with cladribine at 3 to 6 months. In general, response rates and durations of responses have been greater for patients receiving nucleoside analogues as front-line agents, although in several of the above studies in which both untreated and previously treated patients were enrolled, no substantial difference in the overall response rate was reported. Myelosuppression commonly occurred after prolonged exposure to either of the nucleoside analogues, as did lymphopenia with sustained depletion of both CD4$^+$ and CD8$^+$ T lymphocytes 1 year after initiation of therapy. Treatment-related mortality from myelosuppression or opportunistic infections attributable to immunosuppression occurred in up to 5% of all treated patients in some series receiving either nucleoside analogue. Factors predicting a response to nucleoside analogues in therapy included age (younger than 70 years), pretreatment hemoglobin greater than 95 g/L, platelets greater than 75,000/mm^3, disease relapsing while off therapy, patients with resistant disease within the first year of diagnosis, and a long interval between first-line therapy and initiation of a nucleoside analogue in relapsing patients. There are limited data on the use of an alternate nucleoside analogue to salvage patients with disease that relapsed while on therapy or relapsed after discontinuation of the particular agent.[143,144] Three of four (75%) patients responded to cladribine to salvage patients who progressed after an unmaintained remission to fludarabine, but only one of 10 (10%) with disease resistant to fludarabine responded to cladribine.[143] However, Lewandowski et al[150] reported a response in two of six patients (33%) and disease stabilization in the remaining patients to fludarabine despite an inadequate response or progressive disease after cladribine therapy. The combination of nucleoside analogues with cyclophosphamide, rituximab, or both has been investigated and is discussed below.

The safety of nucleoside analogues has been the subject of investigation in several recent studies. Thomas et al recently reported their experiences in harvesting stem cells in 21 patients with symptomatic WM in whom autologous peripheral blood stem cell collection was attempted. Autologous stem cell collection succeeded on the first attempt in 14 of 15 patients who received non-nucleoside analogue–based therapy versus two of six patients who received a nucleoside analogue.[151] The long-term safety of nucleoside analogues in WM was recently examined by Leleu et al[131] in a large series of WM patients. A sevenfold increase in transformation to an aggressive lymphoma and a threefold increase in the development of AML or myelodysplasia were observed among patients who received a nucleoside analogue versus other therapies for their WM. A recent meta-analysis by Leleu et al[152] of several trials using nucleoside analogues in WM patients, which included patients who had previously received an alkylator agent, showed a crude incidence of 6.6% to 10% for development of disease transformation and 1.4% to 8.9% for development of myelodysplasia or AML. None of the studied risk factors—gender, age, family history of WM or B-cell malignancies, typical markers of tumor burden and prognosis, type of nucleoside analogue therapy (cladribine versus fludarabine), time from diagnosis to nucleoside analogue use, nucleoside analogue treatment as primary or salvage therapy—as well as treatment with an oral alkylator (i.e., chlorambucil) predicted for the occurrence of transformation or development of myelodysplasia or AML for WM patients treated with a nucleoside analogue.

Monoclonal Antibodies

Rituximab is a chimeric monoclonal antibody that targets CD20, a widely expressed antigen on lymphoplasmacytic cells in WM.[153] The use of rituximab at standard doses (i.e., 4 weekly infusions at 375 mg/m^2) induces major responses in approximately 27% to 35% of previously treated and untreated patients.[154,155] However, patients who achieved even minor responses benefited from rituximab as evidenced by improved hemoglobin and platelet counts and reduction of lymphadenopathy or splenomegaly.[154] The median time to treatment failure in these studies was found to range from 8 to more than 27 months. Studies evaluating an extended rituximab schedule consisting of 4 weekly courses at 375 mg/m^2/wk repeated 3 months

later by another 4-week course have demonstrated higher major response rates of 44% to 48% with time to progression estimates of more than 16 to more than 29 months.[156,157]

In many WM patients, a transient increase of serum IgM (IgM flare) may be noted immediately after initiation of rituximab treatment.[117-119] The IgM flare may be related to release of IL-6 by bystander immune in response to binding of rituximab to FcγRIIA receptors and also occurs in response to intravenous immunoglobulin administration in WM patients.[158] The IgM flare in response to rituximab does not herald treatment failure, and although most patients will return to their baseline serum IgM level by 12 weeks, some patients may flare for months despite having tumor responses in their BM. Patients with baseline serum IgM levels of greater than 50 g/dL or serum viscosity of greater than 3.5 cp may be particularly at risk for a hyperviscosity-related event, and in such patients, plasmapheresis should be considered or rituximab omitted for the first few cycles of therapy until IgM levels decline to safer levels.[110] Because of the decreased likelihood of response in patients with higher IgM levels as well as the possibility that serum IgM and viscosity levels may abruptly rise, rituximab monotherapy should not be used as sole therapy for the treatment of patients at risk for hyperviscosity symptoms.

Time to response after rituximab is slow and exceeds 3 months on the average. The time to best response in one study was 18 months.[157] Patients with baseline serum IgM levels of less than 60 g/dL are more likely to respond irrespective of the underlying BM involvement by tumor cells.[156,157] A recent analysis of 52 patients who were treated with single-agent rituximab has indicated that the objective response rate was significantly lower in patients who had either low serum albumin (<35 g/L) or elevated serum monoclonal protein (>40 g/L M-spike). Furthermore, the presence of both adverse prognostic factors was related with a short time to progression (3.6 months). Moreover, patients who had normal serum albumin and relatively low serum monoclonal protein levels derived a substantial benefit from rituximab with a time to progression exceeding 40 months.[159]

The genetic background of patients may also be important for determining response to rituximab. A correlation between polymorphisms at amino acid position 158 in the FcγRIIIa receptor (CD16) and rituximab response has been observed in WM patients. WM patients who carry a valine amino acid (either in a homozygous or heterozygous pattern) at this polymorphic site had a fourfold higher major response rate to rituximab versus patients who expressed phenylalanine in a homozygous pattern.[160] The attainment of better categorical responses (i.e., VGPR or complete response [CR] after rituximab-based therapy) appears also dependent on the presence of at least one valine amino acid at FcγRIIIa-158.[113]

Ofatumumab is a fully humanized CD20-directed monoclonal antibody that targets the small loop of CD20, a target that is different than that of rituximab. A 59% overall response rate was observed in a series of 37 symptomatic WM patients after ofatumumab administration, which included untreated and previously treated patients.[161] Responses were higher among rituximab-naive patients. An IgM flare with symptomatic hyperviscosity was also observed in two patients in this series who required plasmapheresis. Ofatumumab has also been successfully administered to WM patients who demonstrated intolerance to rituximab.[162,163]

The activity of alemtuzumab has also been investigated in WM patients given the broad expression of CD52.[154] A multicenter study was recently completed in symptomatic WM patients who had received a median of two (range, 0-5) prior therapies; 43% had refractory disease.[163] Patients received alemtuzumab intravenously at 30 mg three times weekly for up to 12 weeks after test dosing and received hydrocortisone, acyclovir, and Bactrim or equivalent prophylaxis. The overall response rate in this series was 75% and included major responses in 36% of patients. With a median follow-up of 64 months, the median time to progression was 14.5 months. Hematologic and infectious complications, including cytomegalovirus reactivation, were more common in previously treated patients and indirectly associated with three deaths. Long-term follow-up revealed late-onset thrombocytopenia in four patients at a median of 13.6 months after therapy, which contributed to one death. High rates of response with the use of alemtuzumab were also observed by Owen et al,[164] who reported their preliminary experience in a small series of heavily pretreated WM patients. The median number of prior therapies in this series was four, and similar to this study, patients received up to 12 weeks of therapy (at 30 mg IV three times weekly) after initial dose escalation. Among the seven patients treated with alemtuzumab, five achieved a partial response and one a CR. Disseminated *Aspergillus* and mycobacterial infections contributed to two deaths in this series.

Bortezomib

Bortezomib is a proteasome inhibitor that has been extensively investigated in WM. In a multicenter study, 27 patients received up to 8 cycles of bortezomib at 1.3 mg/m^2 on days 1, 4, 8, and 11.[120] All but one patient had relapsed or refractory disease. After therapy, the median serum IgM levels declined from 4660 mg/dL to 2092 mg/dL (P <.0001). The overall response rate was 85%, with 10 and 13 patients achieving minor (<25% decrease in IgM) and major (<50% decrease in IgM) responses. Responses were prompt and occurred at a median of 1.4 months. The median time to progression for all responding patients was 7.9 (range, 3-21.4+) months, and the most common grade III/IV toxicities occurring in 5% or more of patients were sensory neuropathies (22.2%), leukopenia (18.5%), neutropenia (14.8%), dizziness (11.1%), and thrombocytopenia (7.4%). Importantly, sensory neuropathies resolved or improved in nearly all patients after cessation of therapy. As part of an NCI-Canada study, Chen et al[165] treated 27 patients with 44% being untreated and 56% being previously treated. Patients in this study received bortezomib using the standard schedule until they either demonstrated progressive disease or were 2 cycles beyond a CR or stable disease. The overall response rate in this study was 78%, with major responses being observed in 44% of patients. Sensory neuropathy occurred in 20 patients, five with grade above 3, and occurred after 2 to 4 cycles of therapy. Among the 20 patients developing a neuropathy, 14 patients resolved, and one patient demonstrated a one-grade improvement at 2 to 13 months. In addition to the above experiences with bortezomib monotherapy, Dimopoulos et al[166] observed major responses in six of 10 (60%) previously treated WM patients, and Goy et al[167] observed a major response in one of two WM patients who were included in a series of relapsed or refractory patients with non-Hodgkin lymphoma (NHL). The combination of bortezomib with steroids or rituximab has also been investigated and is discussed later.

Immunomodulatory Agents

Thalidomide as monotherapy and in combination with dexamethasone or clarithromycin has been examined. Dimopoulos et al[168] demonstrated a major response in five of 20 (25%) previously untreated and treated patients who received single-agent thalidomide. Dose escalation from the thalidomide starting dose of 200 mg/day was hindered by development of side effects, including the development of peripheral neuropathy in five patients, obligating discontinuation or dose reduction. Low doses of thalidomide (50 mg orally daily) in combination with dexamethasone (40 mg orally once a week) and clarithromycin (250 mg orally twice a day) have also been examined, with 10 of 12 (83%) previously treated patients demonstrating at least a major response.[169] However, in a follow-up study by Dimopoulos et al[170] using a higher thalidomide dose (200 mg orally daily) along with dexamethasone (40 g orally once a week) and clarithromycin (500 mg orally twice a day), only two of 10 (20%) previously treated patients responded. Thalidomide and lenalidomide have also been investigated in combination with rituximab.

Bendamustine

Bendamustine is a recently approved agent for the treatment of relapsed/refractory indolent NHL. Bendamustine has structural

similarities to both alkylating agents and purine analogs.[171] Bendamustine in combination with rituximab has been investigated in both previously untreated, as well as relapsed or refractory WM patients.

Everolimus

Everolimus is an oral inhibitor of the mTOR (mammalian target of rapamycin) pathway, which is approved for the treatment of renal cell carcinoma. The Akt-mTOR-p70 pathway is active in WM, and inhibition of this pathway leads to apoptosis of primary WM cells and WM cell lines.[172,173] Fifty patients with a median of three prior therapies were treated with everolimus in a joint Dana Farber and Mayo Clinic study.[174] The overall response rate was 70%, with 42% of patients attaining a major response. The PFS at 12 months was estimated to be 62%. Grade 3 or higher drug-related toxicities were observed in 56% of patients, with cytopenias constituting the most common. Pulmonary toxicity occurred in 10% of patients. Dose reductions because of toxicity occurred in 52% of patients.

A clinical trial examining the activity of everolimus in previously untreated patients with WM was completed.[175] Although 67% of patients achieved at least a minor response by consensus criteria that rely on paraprotein reduction, IgM discordance to underlying disease burden was seen in up to half of patients in this study. Cytopenias, particularly anemia and thrombocytopenia, were common, and pneumonitis occurred in 15% of patients.

Combination Strategies

Because rituximab is an active and a non-myelosuppressive agent, combination therapy with various chemotherapeutic agents has been extensively explored in WM. The combination of CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) with rituximab (CHOP-R) was investigated in a randomized frontline study by the German Low Grade Lymphoma Study Group (GLSG) involving 69 patients, most of whom had WM.[175] The addition of rituximab to CHOP resulted in a higher overall response rate (94% versus 67%) and median time to progression (63 versus 22 months) compared with patients treated with CHOP alone. Dimopoulos et al[176] investigated the combination of rituximab, dexamethasone, and oral cyclophosphamide (RCD) as primary therapy in 72 patients with WM. At least a major response was observed in 74% of patients in this study, and the 2-year PFS was 67%. Therapy was well tolerated, but one patient died of interstitial pneumonia. The use of CHOP-R has also been investigated in relapsed or refractory WM patients.[177] Among 13 evaluable patients, 10 patients achieved a major response (77%), including three CR and seven partial response (PR), and two patients achieved a minor response. In a retrospective study, Ioakimidis et al[112] examined the outcomes of symptomatic WM patients who received CHOP-R, CVP-R, or CP-R. Baseline characteristics for all three cohorts were similar for age, prior therapies, BM involvement, hematocrit, platelet count, and serum β-2 microglobulin, although serum IgM levels were higher in patients treated with CHOP-R. The overall response rates to therapy were comparable for all three treatment options: CHOP-R (96%), CVP-R (88%), and CP-R (95%), although more CRs were observed among patients treated with either CVP-R or CHOP-R. Comparison of adverse events for these regimens showed a higher incidence of neutropenic fever as well as treatment related neuropathy in patients receiving CHOP-R and CVP-R versus CPR. These results suggest that in WM, the use of doxorubicin and vincristine may be omitted to minimize treatment-related complications.

Combination therapy with nucleoside analogues has also been investigated as both frontline and salvage therapy. Weber et al[178] administered rituximab along with cladribine and cyclophosphamide to 17 previously untreated patients with WM. At least a partial response was documented in 94% of WM patients, including a CR in 18%. With a median follow-up time of 21 months, no patient has relapsed. Laszlo et al[179] recently evaluated the combination of subcutaneous cladribine with rituximab in 29 WM patients who had either untreated or previously treated disease. Therapy consisted of rituximab on day 1 followed by subcutaneous cladribine 0.1 mg/kg for 5 consecutive days, administered monthly for 4 cycles. With a median follow-up of 43 months, the overall response rate observed was 89.6%, with seven CRs, 16 partial responses, and three minor responses. The therapeutic activity was similar between untreated and previously treated patients. No major infections were observed despite the lack of antimicrobial prophylaxis. In a study by the Waldenström Macroglobulinemia Clinical Trials Group (WMCTG), the combination of rituximab and fludarabine was administered to 43 WM patients, 32 (75%) of whom were previously untreated.[114] The overall response rate was 95.3%, and 83% of patients achieved a major response. The median time to progression was 51.2 months in this series and was longer for patients who were previously untreated and for those achieving at least a VGPR. Hematologic toxicity was common, particularly neutropenia and thrombocytopenia. Two deaths occurred in this study because of pneumonia not attributed to *Pneumocystis carinii* infection. Secondary malignancies, including transformation to aggressive lymphoma and development of myelodysplasia or AML, were observed in six patients in this series. The addition of rituximab to fludarabine and cyclophosphamide has also been explored in the salvage setting by Tam et al[180] wherein four of five patients demonstrated a response. Hensel et al[181] administered rituximab along with pentostatin and cyclophosphamide to 13 patients with untreated and previously treated WM or LPL. A major response was observed in 77% of patients. The addition of alkylating agents to nucleoside analogues has also been explored in WM. Weber et al[178] administered 2 cycles of oral cyclophosphamide along with subcutaneous cladribine to 37 patients with previously untreated WM. At least a partial response was observed in 84% of patients, and the median duration of response was 36 months. Dimopoulos et al[182] examined fludarabine in combination with intravenous cyclophosphamide and observed partial responses in six of 11 (55%) patients with either primary refractory disease or patients who relapsed on treatment. The combination of fludarabine plus cyclophosphamide was also evaluated in a study by Tamburini et al[183] involving 49 patients, 35 of whom were previously treated. Seventy-eight percent of the patients in this study achieved a response, and the median time to treatment failure was 27 months. Hematologic toxicity was commonly observed, and three patients died of treatment-related toxicities. In this study, leukemia developed in two patients, histologic transformation to diffuse large cell lymphoma occurred in one patient, and two cases of solid tumors (prostate and melanoma) were observed. In addition, four of six patients failed to mobilize their stem cells in sufficient numbers to serve as a stem cell graft. Tedeschi et al[184] recently completed a multicenter study of fludarabine, cyclophosphamide, and rituximab in symptomatic WM patients with untreated or relapsed or refractory disease to one course of prior chemotherapy. Treatment consisted of rituximab at 375 mg/m^2 on day 1 and fludarabine at 25 mg/m^2 and cyclophosphamide at 250 mg/m^2 by intravenous administration on days 2 to 4 every 4 weeks. The overall response rate in patients was 89%, with 83% of patients attaining a major remission and 14% a CR. Prolonged neutropenia was observed in up to one-third of patients. With a median follow-up time of 15 months, the median PFS for this study has not been reached.

The combination of bortezomib, dexamethasone, and rituximab (BDR) has been investigated as frontline therapy in patients with WM by the WMCTG. An overall response rate of 96%, major response rate of 83%, and complete remission in 22% was observed with BDR.[115] The updated median PFS in this study was more than 56.1 months. The incidence of grade 3 neuropathy was 30% in this study, which used a twice-a-week schedule for bortezomib administration at a dose of 1.3 mg/m^2. Peripheral neuropathy from bortezomib was reversible in most patients in this study after discontinuation of therapy. An increased incidence of herpes zoster infections was also observed with BDR, prompting the use of prophylactic antiviral therapy. An alternative schedule for bortezomib administration (i.e., weekly at 1.6 mg/m^2) in combination with rituximab or dexamethasone (or both) has been investigated in several studies with overall response rates of 80% to 90% being achieved.[185-187] A lower incidence

of peripheral neuropathy was observed in two studies using once-a-week bortzomib.[182,187] The impact of once- versus twice-a-week bortezomib administration on PFS remains to be documented.

The combination of immunomodulatory agents (thalidomide, lenalidomide) with rituximab was investigated by the WMCTG. Thalidomide was administered at 200 mg/day for 2 weeks followed by 400 mg/day, and thereafter thalidomide was continued for 1 year. Patients received four weekly infusions of rituximab at 375 mg/m^2 beginning 1 week after initiation of thalidomide followed by four additional weekly infusions of rituximab at 375 mg/m^2 beginning at week 13. The overall and major response rate was 72% and 64%, respectively, and the median time to progression was 38 months in this series.[124] Dose reduction or discontinuation of thalidomide was common, mainly because of treatment-related neuropathy. The investigators concluded that lower doses of thalidomide (i.e., 50-100 mg/day) should be considered in this patient population. The combination of lenalidomide with rituximab was investigated by the WMCTG with patients receiving lenalidomide 25 mg/day for 3 weeks followed by a 1-week pause for 48 weeks.[125] Patients received 1 week of therapy with lenalidomide, after which rituximab (375 mg/m^2) was administered weekly on weeks 2 to 5 and then 13 to 16. The overall and major response rates in this study were 50% and 25%, respectively, and a median time to progression for responders was 18.9 months. In two patients with bulky disease, a significant reduction in extramedullary disease was observed. However, an acute decrease in hematocrit levels was observed during first 2 weeks of lenalidomide therapy in 13 of 16 (81%) patients with a median absolute decrease in hematocrit of 4.8%, resulting in anemia-related complications and hospitalization in four patients. Despite dose reductions, most patients in this study continued to demonstrate progressive anemia with lenalidomide. There was no evidence of hemolysis or more general myelosuppression with lenalidomide in this study. Therefore, the mechanism for lenalidomide-related anemia in WM patients remains to be determined, and the use of this agent among WM patients should be avoided.

The use of bendamustine in combination with rituximab was explored by Rummel et al[188] as the frontline therapy of WM. As part of a randomized study, patients received 6 cycles of bendamustine plus rituximab (Benda-R) or CHOP-R. A total of 546 patients were enrolled in this study of indolent NHL patients and included 40 patients with WM. Patients on the Benda-R arm received bendamustine at 90 mg/m^2 on days 1 and 2 and rituximab at 375 mg/m^2 on day 1 every 4 weeks. The overall response rate was 96% for Benda-R, and 94% for CHOP-R–treated patients. With a median observation period of 26 months, 20 of 23 (87%) receiving Benda-R versus nine of 17 (53%) receiving CHOP-R remain free of disease progression. Importantly, Benda-R was associated with a lower incidence of grade 3 or 4 neutropenia, infectious complications, and alopecia. In the salvage setting, the outcome of 30 WM patients with relapsed or refractory disease who received bendamustine alone or with a CD20-directed antibody was reported by Treon et al.[189] An overall response rate of 83.3% and a median PFS of 13.2 months were reported in this study. Overall, therapy was well tolerated, although prolonged myelosuppression occurred in patients who received prior nucleoside analogue therapy.

MAINTENANCE THERAPY

A role for maintenance rituximab in WM patients after response to a rituximab-containing regimen was raised in a study examining the outcome of 248 WM rituximab-naive patients who were either observed or received maintenance rituximab.[190] In this retrospective study, categorical responses improved in 16 of 162 (10%) patients not receiving rituximab maintenance and in 36 of 86 (41.8%) patients who received maintenance rituximab after induction therapy. Both PFS (56.3 versus 28.6 months) and overall survival (>120 versus 116 months) were longer in patients who received maintenance rituximab. Improved PFS was evident despite previous treatment status, induction with rituximab alone, or combination therapy. A greater reduction in serum IgM was observed, and hematocrits were higher in patients receiving maintenance rituximab. Among patients receiving maintenance rituximab, an increased number of infectious events, predominantly sinusitis and bronchitis, was observed, but these events were mainly grade 1 or 2.

HIGH-DOSE THERAPY AND STEM CELL TRANSPLANTATION

The use of stem cell transplantation (SCT) therapy has also been explored in patients with WM. Desikan et al[191] reported their initial experience of high-dose chemotherapy and autologous SCT, which has more recently been updated by Munshi et al.[192] Their studies involved eight previously treated WM patients between the ages of 45 and 69 years who received either melphalan at 200 mg/m^2 or at 140 mg/m^2 with total-body irradiation (TBI). Peripheral blood stem cells were successfully collected in all eight patients, but a second collection procedure was required for two patients who had extensive prior nucleoside analogue therapy. There were no transplant-related mortalities, and toxicities were manageable. All eight patients responded, with seven of eight patients achieving a major response and one patient achieving a CR with the duration of response ranging from 5+ to 77+ months. Dreger et al[193] investigated the use of the DEXA-BEAM (dexamethasone, BCNU, etoposide, cytarabine, melphalan) regimen followed by myeloablative therapy with cyclophosphamide and TBI and autologous SCT in seven WM patients, which included four untreated patients. Serum IgM levels declined by more than 50% after DEXA-BEAM and myeloablative therapy for six of seven patients, with PFS ranging from more than 4 to more than 30 months. All three evaluable patients who were previously treated also attained a major response in a study by Anagnostopoulos et al[194] wherein WM patients received various preparative regimens and demonstrated event-free survivals of more than 26, 31, and more than 108 months. Tournilhac et al[195] recently reported the outcome of 18 WM patients in France who received high-dose chemotherapy followed by autologous SCT. All patients were previously treated with a median of three (range, 1-5) prior regimens. Therapy was well tolerated with an improvement in response status observed for seven patients (six PR to CR; one stable disease [SD] to PR), but only one patient demonstrated progressive disease. The median event-free survival for all nonprogressing patients was 12 months. Tournilhac et al[195] have also reported the outcome of allogeneic SCT in 10 previously treated WM patients (ages 35-46 years) who received a median of three prior therapies, including three patients with progressive disease despite therapy. Two of three patients with progressive disease responded, and an improvement in response status was observed in five patients. The median event-free survival for nonprogressing, evaluable patients was 31 months. Of concern in this series was the death of three patients owing to SCT-related toxicity. Anagnostopoulos et al[196] have also reported a retrospective review of WM patients who underwent either autologous or allogeneic SCT, whose outcomes were reported to the International Blood and Marrow Transplant Registry. Seventy-eight percent of patients in this cohort had two or more prior therapies, and 58% of them were resistant to their prior therapy. The relapse rate at 3 years was 29% in the allogeneic SCT group and 24% in the autologous SCT group. Non–relapse-related mortality, however, was 40% in the allogeneic SCT group and 11% in the autologous SCT group in this series.

Kyriakou et al[116] reported on the outcome of WM patients in the European Bone Marrow Transplant (EBMT) registry who received either an autologous or allogeneic SCT. Among 158 patients receiving an autologous SCT, which included primarily relapsed or refractory patients, the 5-year PFS and overall survival rates were 39.7% and 68.5%, respectively. Non–relapse-related mortality at 1 year was 3.8%. Chemorefractory disease, and the number of prior lines of therapy at time of the autologous SCT were the most important prognostic factors for PFS and overall survival. The achievement of a negative immunofixation after autologous SCT had a positive impact on PFS. When used as consolidation at first response,

autologous transplantation provided a PFS of 44% at 5 years. In the allogeneic SCT experience from the EBMT, the long-term outcome of 86 WM patients was reported by Kyriakou.[197] A total of 86 patients received allogenic SCT with either a myeloablative (n = 37) or reduced-intensity (n = 49) conditioning regimen. The median age of patients in this series was 49 years, and 47 patients had three or more previous lines of therapy. Eight patients failed prior autologous SCT. Fifty-nine patients (68.6%) had chemotherapy-sensitive disease at the time of allogeneic SCT. Non–relapse-related mortality at 3 years was 33% for patients receiving a myeloablative transplant and 23% for those who received reduced-intensity conditioning. The overall response rate was 75.6%. The relapse rates at 3 years were 11% for myeloablative and 25% for reduced-intensity conditioning recipients. Five-year PFS and overall survival for WM patients who received a myeloablative allogenic SCT were 56% and 62% and for patients who received reduced intensity conditioning were 49% and 64%, respectively. The occurrence of chronic graft-versus-host disease was associated with improved PFS and suggested the existence of a clinically relevant graft-versus-WM effect in this study.

FUTURE DIRECTIONS

Since the initial description of macroglobulinemia by Jan Gosta Waldenström in 1944, the genetic basis for this disease has remained unknown. The recent finding of a highly recurrent somatic mutation (MYD88 L265P) in WM LPL patients provides not only a potentially useful diagnostic tool but also has important implications for therapy of WM. The use of inhibitors that target MYD88 and IRAK signaling induces apoptosis of MYD88 L265P expressing cells and blocks NFκB signaling.[20] These observations are of particular relevance to WM because NFκB signaling is important for WM growth and survival. Blockade of IκBα by proteasome inhibitors is associated with high rates of responses in WM patients, and direct targeting of tonic MYD88/IRAK signaling imposed by MYD88 L265P may therefore provide a novel approach for WM treatment. Such targeting may also circumvent other growth-promoting pathways upstream of NFkB mediated by p38 MAP kinase (MAPK), signal transducers and activators of transcription 3 (STAT3) and Bruton tyrosine kinase (BTK) that may also be dependent on MYD88.

CHAPTER 87

IMMUNOGLOBULIN LIGHT-CHAIN AMYLOIDOSIS (PRIMARY AMYLOIDOSIS)

Morie A. Gertz, Francis K. Buadi, Steven R. Zeldenrust, and Suzanne R. Hayman

In 1858, Rudolf Virchow described the reaction of amyloid deposits with iodine and sulfuric acid.[1] This reaction was considered a marker for starch; hence Virchow used the term *amyloid,* meaning "starch-like," to describe the deposits. At approximately the same time, Professor Carl Rokitansky in Vienna had recognized lardaceous deposits in the viscera of patients with tuberculosis or syphilis.[2] The white, shiny appearance of these deposits led him to conclude that they were of fat origin. Later, Carl Friedreich recognized that the waxy spleen described by Virchow contained no material structurally similar to cellulose and determined that the deposits were probably albuminoid.[3] Sir Samuel Wilks, the first physician to use bromide in the treatment of epilepsy, reported on a patient who had lardaceous changes of the liver with no obvious cause.[4] This may have been the first reported patient with primary amyloidosis (AL).

Congo red staining of amyloid was introduced by Bennhold in 1922,[5] and in 1927, Divry and Florkin described the green birefringence of amyloid under polarized light.[6] In 1959, Cohen and Calkins[7] recognized that all forms of amyloid had a fibrillar structure when viewed with an electron microscope. In 1968, Eanes and Glenner[8] reported that unlike normal proteins, which have an α-helical configuration, amyloid deposits form a β-pleated sheet, rendering them resistant to the action of solvents. The first purification of amyloid was described by Pras et al[9] in 1968. The first amyloid protein was sequenced in 1970 by Glenner et al,[10] who recognized it as the N-terminus of an immunoglobulin light chain. In 1974, Isobe and Osserman[11] first recognized that the Bence Jones proteins had a role in the pathogenesis of AL.

CLASSIFICATION

All forms of amyloid stain positively with Congo red, and this is the sine qua non for the diagnosis of this disorder. Amyloid deposits appear amorphous and extracellular when stained with hematoxylin and eosin. False-positive results have been reported with Congo red staining, however, and some experience with the technique is desirable.[12] All forms of amyloid are fibrillar in nature; the fibrils are rigid and nonbranching. In the early and mid-20th century, amyloidosis was classified by the anatomic distribution of the amyloid deposits and was assigned to one of three categories.

Familial amyloidosis was recognized by its presentation, which was usually a painful peripheral neuropathy with an autosomal dominant inheritance pattern.[13,14a] Mutations in a number of plasma proteins, including transthyretin (TTR), apolipoprotein AI and AII, fibrinogen A α-chain, and lysozyme, are associated with hereditary systemic amyloidosis. TTR amyloidosis is the most common and is usually associated with peripheral neuropathy. Mutations in the other proteins usually have no neuropathic consequences and instead principally cause renal and cardiac amyloidosis. A completely new form of amyloidosis caused by LECT2 (leukocyte chemotactic factor 2) has recently been described[14b] in a patient presenting with nephrotic syndrome and subsequent azotemia requiring hemodialysis. Over 8 years, 285 renal amyloid samples, of which 31 were unclassifiable by tandem mass spectrometry were found to be LECT2 related in 7.[14c] Isolation of genomic DNA and polymerase chain reaction amplification of LECT2-encoding exons showed no mutations. However, all were homozygous for the G allele encoding valine at position 40 in the mature protein. LECT2-associated renal amyloidosis represents a unique form of renal amyloidosis, especially in Mexican Americans.[14d]

The secondary form of amyloidosis was characterized by an associated long-standing inflammatory disorder. One hundred years ago, this usually represented tuberculosis, leprosy, syphilis, and chronic infection such as bronchiectasis and osteomyelitis. Today in Western countries, amyloidosis is commonly associated with chronic inflammatory polyarthritis syndromes such as ankylosing spondylitis and juvenile rheumatoid arthritis. It is also associated with Castleman disease and Crohn disease. Secondary amyloidosis (AA) is becoming increasingly rare as more effective therapy of inflammatory arthropathies prevents the sustained inflammation necessary for AA to develop.[14e]

Fifty years ago, all forms of amyloidosis that were not secondary or familial were considered "primary." In the original terminology, "primary" meant "idiopathic" and most likely contained a heterogeneous combination of multiple forms of amyloidosis. Today, the term *primary amyloidosis,* or AL, refers to a systemic disorder with amyloid deposits consisting of immunoglobulin light chains or their fragments or heavy chains.

All forms of systemic AL are associated with a clonal disorder of plasma cells, which may range from a small clonal population of 5% plasma cells or less in the bone marrow (BM) to overt multiple myeloma (MM). Table 87-1 contains a modified classification of the more frequently described forms of amyloidosis.

PATHOPHYSIOLOGY

Amyloid fibrils can be produced in vitro by peptic digestion of purified monoclonal human immunoglobulin light chains. The light chains of patients with AL have an abnormal sequence and an abnormal tertiary structure that favors the misfolding into β-pleated sheet configuration. Investigation of the thermodynamic properties of light chains that form fibrils and those that remain stable have shown an inverse relationship between thermodynamic stability and fibrillogenic potential. Structural parameters and overall thermodynamic stability contribute to the fibril-forming propensity of immunoglobulin light chains.[15] When injected into mice, immunoglobulin light chains purified from the urine of patients with AL produce human AL deposits,[16] but light chains from patients with MM (and not AL) do not.

Two-thirds of patients with monoclonal gammopathy of undetermined significance (MGUS) or MM have κ immunoglobulin light chains. Three-fourths of patients with amyloidosis who have a light chain have λ, which reflects the intrinsic "amyloidogenicity" of λ immunoglobulin light chains. The λ_{VI} is always associated with amyloid, suggesting that unique amino acid structures render these proteins amyloidogenic.[17]

A comparison of monoclonal proteins in AL and MM is shown in Fig. 87-1. Amyloid-associated germline gene segments have been identified[18]; the λ_{III} family is found most frequently in amyloidosis. Two germline genes, 3r and 6a, belonging to the λ_{III} and λ_{VI} families contributed equally to encode 42% of amyloid variable λ regions.

Table 87-1 Nomenclature of Amyloidosis

Protein	Precursor	Clinical Characteristics
AL or AH	Immunoglobulin light or heavy chain	Primary or localized; myeloma or macroglobulinemia associated
AA	SAA	Secondary or familial Mediterranean fever, familial periodic fever syndromes
ATTR	Transthyretin	Familial and senile
A fibrinogen	Fibrinogen	Familial renal amyloidosis (Ostertag)
$A\beta_2M$	β_2-Microglobulin	Dialysis associated; carpal tunnel syndrome
Aβ	ABPP	Alzheimer disease
A Apo A-I/A-II	Apolipoprotein A-I Apolipoprotein A-II	Proteinuria Cardiac Neuropathy
A lysozyme	Lysozyme	GI tract Liver Renal
ALECT2	Renal

These same two gene segments have a strong association with amyloidosis and are most likely responsible for the λ light-chain overrepresentation typical of amyloidosis.[18]

The reason that patients with AL present with amyloid disease displaying organ tropism is unknown. The renal tropism of some chains was investigated.[19] Patients with clones derived from the 6a variable λ_{VI} germline gene were more likely to present with renal involvement. Those with clones derived from the 1c, 2a2, and 3r variable λ genes were more likely to present with dominant cardiac and multisystem disease. Patients with variable κ clones were more likely to have dominant liver involvement.[19]

The classification of AL among patients with and without myeloma is usually made on the basis of clinical criteria, but considerable clinical overlap exists. The presence of MM bone disease, such as lytic lesions, multiple compression fractures, or pathologic fractures of long bones, is rare in AL. Patients with AL and renal insufficiency rarely have myeloma cast nephropathy. Renal failure in these patients is usually tubular atrophy from glomerular amyloid and long-standing albuminuria. The percentage of BM plasma cells is useful in making the distinction between AL and myeloma. At Mayo Clinic, we have arbitrarily defined patients as having MM–associated amyloidosis if the BM plasma cells exceed 30%.[20a] Routine Congo red staining of myeloma BM samples is not indicated.[20b] Amyloidosis rarely evolves into overt MM; it occurs in fewer than 0.5% of patients.[20a]

The incidence of amyloidosis is eight per million persons per year and is not increasing with time.[21] Amyloidosis is one-fifth as common as MM but has an incidence similar to those of nodular sclerosing Hodgkin disease, chronic myeloid leukemia, and polycythemia vera.

Chromosomal anomalies are seen often in the BM plasma cells of patients with AL.[22] Studies of BM samples found trisomies involving chromosomes 7, 9, 11, 15, and 18 in 42%, 52%, 47%, 39%, and 33% of patients, respectively. Trisomy X was seen in 13% of women and 54% of men. Monosomy of chromosome 18 was seen in 72%. This aneuploidy supports the neoplastic nature of the disorder even though it is not proliferative over time. Fluorescence in situ hybridization (FISH) analysis of the plasma cells of AL patients showed that 16 of 29 (55%) had a definite immunoglobulin heavy-chain translocation, and five additional patients (17%) had a pattern compatible with heavy-chain translocation.[23] Sixteen of 21 patients were confirmed to have t(11;14)(q13;q32), accounting for 76% of all immunoglobulin heavy-chain translocations.[24a] Seventy percent of AL patients had abnormal cIg-FISH, with the most common abnormalities being IgH translocations (48%)—including t(11;14) [39%], and t(14;16) [2%]—and del13/del13q [30%]. The risk of death for patients harboring the t(11;14) translocation was 2.1.[24b] Fifteen of 16 patients with an 11;14 translocation had cyclin D1 overexpression. In a second study translocation t(11;14) was the most frequent aberration in AL, with 47% versus 26% in MGUS (P = .03), and was strongly associated with the lack of an intact immunoglobulin (P < .001), thus contributing to the frequent light-chain subtype in AL.[24b]

CLINICAL FEATURES

The most common presenting symptoms of amyloidosis are fatigue, dyspnea, edema, paresthesias, and weight loss.[25] The symptoms are generally not specific and not particularly helpful in formulating the differential diagnosis. Weight loss usually results in an investigation for occult malignancy. The fatigue can be misdiagnosed as functional or stress related. Patients with dyspnea on exertion regularly undergo coronary angiography; in most, no coronary artery disease is seen, and the evaluation is halted. Lightheadedness is common but nonspecific. Hypotension is seen in patients with nephrotic syndrome because the hypoalbuminemia results in reduced oncotic pressure and contraction of the plasma volume. In cardiac AL, the stiffened heart has poor diastolic filling.[26a] This results in a reduced cardiac output with a normal ejection fraction on echocardiography. The septal thickening is attributed inappropriately to silent hypertension, and the patient lacks cardiomegaly, all of which conspire to obscure the correct diagnosis.[26b] The stroke volume decreases, resulting in a decrease in systolic blood pressure. Amyloid autonomic neuropathy also leads to orthostatic lightheadedness and occasionally syncope.[27]

The physical findings of amyloidosis can be highly specific but are only present in a minority of patients. Amyloid purpura is typical but is seen in only one-sixth of patients. The purpura occurs above the nipple line and is seen in the webbing of the neck, the face, and the eyelids (Fig. 87-2). The purpura may be subtle and limited to eyelid petechial lesions. Hepatosplenomegaly is seen in 25% of patients but more than 5 cm below the right costal margin in 10% of patients.[28] The presence of macroglossia is highly specific for AL[29]; it is not seen in familial, secondary, or senile systemic amyloidosis. Only one patient in 11 has an enlarged tongue; it can be overlooked because

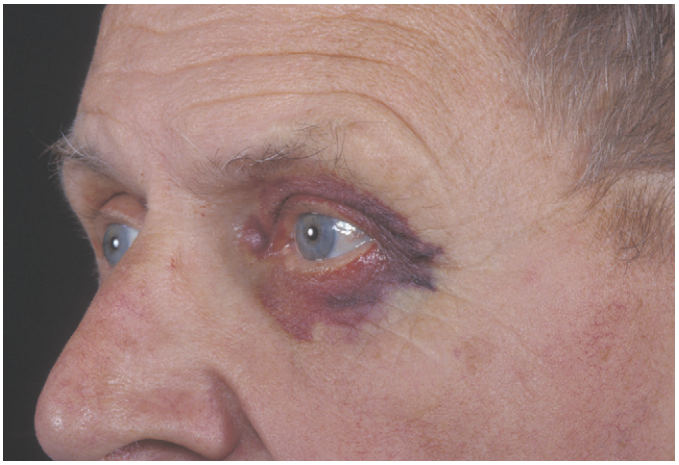

Figure 87-2 CLASSIC PERIORBITAL PURPURA ASSOCIATED WITH AMYLOIDOSIS.

Figure 87-3 MASSIVE ENLARGEMENT OF THE TONGUE CAUSED BY AMYLOID INFILTRATION. This patient had severe obstructive sleep apnea; was unable to swallow solid food; and had obstructed eustachian tubes, leading to bilateral serous otitis media.

the most common finding is dental indentations on the underside of the tongue, which may not be inspected during a routine physical examination. If the tongue is enlarged, the submandibular salivary glands are also palpable (Fig. 87-3), which can be misinterpreted as submandibular lymph nodes. Salivary gland infiltration with amyloid can produce a sicca syndrome, and patients can be misdiagnosed as having Sjögren syndrome.[30]

Patients can be seen with diffuse vascular involvement without obvious visceral disease. Involvement of the small vessels supplying blood to major muscle groups can produce vascular occlusion and ischemic symptoms that include jaw,[31] calf, and limb claudication. Involvement of the coronary arteriolar system can produce true exertional angina without evidence of large vessel coronary disease. In one study, obstructive intramural coronary amyloidosis was found in 63 of 96 patients.[31] Myocardial ischemia was more common in patients with obstructive intramural coronary amyloidosis than those without (86% vs. 52%). Syndromes of myocardial ischemia affected

Table 87-2 Syndromes in Primary Amyloidosis

Syndrome	Patients (%)
Nephrotic or nephrotic and renal failure	30
Hepatomegaly	24
Congestive heart failure	22
Carpal tunnel	21
Neuropathy	17
Orthostatic hypotension	12

25% of patients with obstructive intramural coronary amyloidosis.[32] For 11% of these patients, a syndrome of ischemia consisting of acute myocardial infarction or angina was the first manifestation of AL.

Most patients with AL and cardiac involvement have obstructive intramural coronary amyloidosis and associated changes of myocardial ischemia.[31] The presence of jaw claudication has led to an incorrect diagnosis of polymyalgia rheumatica.[33] Other manifestations of nonvisceral soft tissue infiltration include skeletal muscle pseudohypertrophy, which can produce the shoulder-pad sign.[34] Despite the enlargement of the muscles, patients frequently have diffuse muscular weakness and atrophy.[35] The creatine kinase concentration may be increased, which results in a misdiagnosis of polymyositis or inflammatory myopathy syndrome.

ESTABLISHING THE DIAGNOSIS OF AMYLOIDOSIS

The subjective symptoms associated with amyloidosis are vague.[36] The physical findings with AL may be highly specific but are present in only 15% of patients. Given that AL is rare, when should a clinician suspect this diagnosis and begin a diagnostic evaluation to confirm the diagnosis? The eight most common clinical syndromes associated with amyloidosis are (1) infiltrative cardiomyopathy manifesting as a spectrum from fatigue to overt congestive heart failure, (2) albuminuria with or without renal insufficiency, (3) peripheral neuropathy with demyelinating or axonal features, (4) unexplained hepatomegaly, (5) carpal tunnel syndrome, (6) enlargement of the tongue, (7) weight loss associated with intestinal symptoms of pseudo-obstruction or malabsorption, and (8) "atypical myeloma" (Table 87-2). If any of these syndromes are seen in an adult, AL enters the differential diagnosis.

Because of the presence of a monoclonal protein, patients are often extensively evaluated for MM but are found to have less than 10% plasma cells and no lytic bone lesions, and a diagnosis of AL frequently is not considered by the clinician. These patients are often mislabeled as having MGUS or myeloma with atypical features. By definition, patients with systemic AL have a clonal population of plasma cells that produces the immunoglobulin light chain comprising the amyloid deposits. The finding of a monoclonal protein in a patient with a compatible syndrome would be compelling evidence for pursuing a diagnosis of AL (Fig. 87-4).

If a patient has one of the clinical syndromes outlined above, a sensitive and noninvasive screening test for AL should be used. Simple serum protein electrophoresis is not an adequate screen. The monoclonal proteins in patients with AL are frequently either small or limited to free light chains that do not produce a peak after the electrophoresis. In addition, a high proportion of patients has significant albuminuria, which can obscure the presence of small monoclonal proteins in the urine (Fig. 87-5).

A serious consideration of AL requires immunofixation of serum and urine; urine immunofixation is mandatory because 25% of patients do not have detectable light chains in the serum by immunofixation. By this method, a monoclonal light chain will be detected

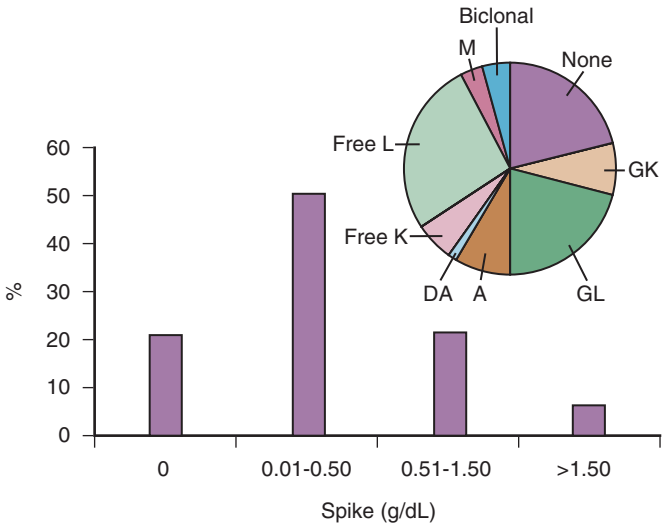

Figure 87-4 SERUM MONOCLONAL PROTEIN CONCENTRATION IN PATIENTS WITH PRIMARY AMYLOIDOSIS. Pie chart shows distribution of serum immunofixation results ($n = 434$). *A,* Monclonal IgA protein in serum; *Biclonal,* two different monclonal proteins in serum; *DA,* monclonal IgD protein in serum; *GK,* monclonal IgG kappa protein in serum; *GK,* monclonal IgG kappa protein in serum; *Free L,* monoclonal lambda light chain in serum; *Free K,* monoclonal kappa light chain in serum; *M,* monclonal IgM protein in serum; *None,* no monoclonal protein serum. *(From Gertz MA, Lacy MQ, Dispenzieri A: Amyloidosis. in 90% of patients with AL. Adding the free light-chain nephelometric assay increases the detection rate to 99%. The nephelometric assay for free light chains is more sensitive than immunofixation by at least a factor of 10. Quantification of monoclonal free light chains by nephelometry is more sensitive than immunofixation in serum samples from patients with AL and light-chain deposition disease. This method allows quantification of free light chains in patients who have no detectable serum or urine monoclonal protein.[37]

Immunofixation of serum and urine combined with a free light-chain assay is the best noninvasive screening panel when a patient is seen with a suggestive clinical syndrome. In patients who do not have a detectable light chain in the serum or urine, a BM specimen will almost always demonstrate a clonal population of plasma cells by immunohistochemistry or immunofluorescence. If these study results are negative, the patient does not have amyloidosis (false-positive Congo red stain) or the detected amyloid deposit is localized, or if the amyloid is systemic, then it is secondary or familial.

Virtually all patients with systemic AL have a monoclonal protein in the serum or urine or clonal BM plasma cells. If no immunoglobulin light chain is found in a patient with proven amyloidosis, other types of amyloidosis should be suspected, including familial, secondary, and localized. The presence of a monoclonal protein does not unequivocally prove that the amyloidosis type is AL. Three percent of patients older than 60 years have an incidental MGUS.[38a] It is therefore reasonable to believe that 3% of patients older than 60 years with localized, secondary, and familial amyloidosis have an incidental monoclonal protein in the serum. Case reports exist of patients with low-level monoclonal gammopathies associated with a nonimmunoglobulin form of amyloidosis. The possibility, albeit uncommon, of an incidental monoclonal gammopathy unrelated to the patient's amyloidosis must be kept in mind. The authors have recently reported some of the more common diagnostic errors encountered when a patient is undergoing evaluation for amyloidosis.[38b]

A nephelometric technique for analyzing circulating immunoglobulin light chains in the serum recognizes only free immunoglobulin light chains and not those that are part of the intact immunoglobulin molecule.[39,40] A study of approximately 100 patients using antibodies specific for free immunoglobulin light chains showed a sensitivity of nearly 90% for the nephelometric technique.[41] The sensitivity was the same for patients with κ and λ amyloid. In patients who had a known monoclonal light chain in the urine but negative serum immunofixation results, free light chains were detected in 85% of patients with κ and 80% of patients with λ. In a carefully evaluated group of patients with definite AL who had no detectable monoclonal protein in the serum or urine by immunofixation, a free light chain was found in 86% and a free λ light chain in 30%.[41]

The nephelometric method assists in classification of patients with amyloidosis as having AL.[42] Patients with familial, secondary, or localized amyloidosis are not expected to have an abnormal ratio of free light chains in the serum. If the serum free light-chain assay and serum and urine immunofixation results are all negative or normal, the likelihood of a diagnosis of AL is small.

The free light-chain assay also is useful in assessing the outcome of treatment of amyloidosis. Free light-chain criteria have now been incorporated into the response criteria. The proposed new criteria require a partial response to reflect a greater than 50% decrease in the difference between involved and uninvolved immunoglobulin light chain before and after therapy. A very good partial response would be defined as a difference in the involved and uninvolved immunoglobulin free light chain of less than 4 mg/dL after therapy, and a complete response would be negative immunofixation serum and urine and a normal free light-chain ratio.[43a] Eighty-six patients whose abnormal free light-chain concentration decreased by more than 50% after chemotherapy had a 5-year survival rate of 88% compared with only 39% among patients for whom the free light-chain concentration did not decrease similarly.[43b] The conclusion was that decrease in the free light chain by more than 50% after chemotherapy is associated with a substantial survival benefit.

The amyloid P component is a glycoprotein that comprises as much as 10% of the amyloid fibril by weight.[44] All forms of amyloid contain the P component. The amyloid P component is related structurally to C-reactive protein, an acute-phase reactant used in the screening of patients at risk for coronary artery disease. The amyloid P component is not irreversibly bound to the amyloid fibril but is in dynamic equilibrium with the normal plasma amyloid P component compartment.[45] It is found in all humans and maintains a stable plasma level throughout life.

Radiolabeled amyloid P component—with iodine 123[46] or iodine 131[47]—is a useful imaging agent for identifying amyloid deposits. Serialized serum amyloid P scintigraphic scans have

Used with permission.)*

been used to assess the response to therapy and have shown regression of established amyloid deposits after successful interruption of immunoglobulin light-chain production.[48] This scan does not distinguish AL from the other forms of amyloidosis. Imaging indicates deposits in the spleen, liver, and kidneys in 87%, 60%, and 25% of patients, respectively.[49] Because of the cardiac blood pool, this technique is not useful in detecting myocardial amyloid deposits and is usually used in conjunction with echocardiography. The diagnostic sensitivity of serum amyloid P scintigraphy for AL is 90%, and specificity is 93%.[50] Myocardial uptake is not visualized in any patient. Splenic amyloid is present in 80% of patients even though it is rarely detected clinically (15%). Tracer uptake in the liver and kidneys correlates with abnormal liver function and proteinuria. BM uptake is specific for AL but is only seen in 21%.[50]

Plasma clearance of the amyloid P component has been shown to correlate with survival. Rapid plasma clearance is associated with high body burdens of amyloid and shortened survival. Scintigraphic scans have shown that the distribution of amyloid within organs is nonhomogeneous, and imaging studies do not correlate well with the clinical degree of organ dysfunction.[51] Most patients have hepatic involvement by serum amyloid P scan, but palpable hepatomegaly with increased concentration of alkaline phosphatase is seen in no more than 15% of patients. Therapeutic clinical trials of agents that prevent the binding of amyloid P component to the amyloid fibril have been started.[52a] The rationale is that inhibition of P component binding may destabilize the fibrillar structure of amyloid and result in more rapid catabolism by the body. Administration of anti–human-SAP antibodies to mice with amyloid deposits containing human SAP triggers a potent, complement-dependent, macrophage-derived giant cell reaction that swiftly removes massive visceral amyloid deposits without adverse effects. Anti-SAP antibody treatment is clinically feasible because circulating human SAP can be depleted in patients by the bis-d-proline compound CPHPC, thereby enabling injected anti-SAP antibodies to reach residual SAP in the amyloid deposits.[52b]

Although the presence of immunoglobulin free light chains, positive immunofixation results, or positive amyloid P component scans is highly suggestive of the diagnosis of AL, these findings are not substitutes for histologic confirmation of the disease. Amyloidosis is a serious life-threatening disorder, and some of the currently available therapies carry a considerable morbidity and mortality risk. Given the serious prognosis and potential for administering toxic therapies, a biopsy-proven diagnosis is vital. Although the presence of renal, cardiac, hepatic, or peripheral nerve amyloid is easily established by direct biopsy of these tissues, invasive diagnostic biopsies of these tissues are generally not required. Amyloidosis is a widespread disorder at diagnosis, with involvement of blood vessels even in the absence of clinical symptoms. Any biopsy that samples blood vessels can less invasively establish the diagnosis effectively and at a lower risk to the patient.

At the Mayo Clinic, if a patient has a compatible clinical syndrome and screening suggests the presence of a free or monoclonal immunoglobulin light chain, the first diagnostic technique is generally subcutaneous fat aspiration[53] combined with BM biopsy. The fat aspiration procedure performed by the authors' nursing staff is risk free, and no infection at the site of puncture has occurred. Results are generally available in 24 to 48 hours, and the technique has a sensitivity of nearly 80% (Table 87-3). Thorough examination of three fat smears showed a sensitivity of 93% and a specificity of 100% for the test. The clinical utility of fat tissue aspiration was greater than that of a rectal biopsy.[54a] Fat aspiration is the preferred method for detecting amyloidosis, with a sensitivity of 80% using a routine approach and 90% with a thorough assessment by experienced interpreters.[54a] The amount of amyloid in subcutaneous fat tissue in systemic amyloidosis reflects disease severity, as measured by the number of organs involved, and predicts decreased survival independent of other well-known factors.[54b]

A BM biopsy shows amyloid deposits in half of patients if the biopsy specimen contains blood vessels.[55] A BM biopsy is generally required because after a monoclonal protein has been found, determining the percentage of BM plasma cells is vital to exclude the diagnosis of MM (Figs. 87-6 and 87-7, *A*). In the authors' experience, 90% of patients with AL have positive results with a subcutaneous fat aspiration and BM biopsy.

Others have reported success using rectal biopsies[56] (Fig. 87-7, *B*), gingival biopsies, and minor salivary gland biopsies.[57] If noninvasive biopsies do not establish the diagnosis, biopsy of the affected organ can generally be performed quite safely. Endomyocardial biopsy is an outpatient procedure and can be done with low risk in experienced centers. Despite reports to the contrary, liver biopsy is exceedingly safe, with no reported fatalities in the authors' experience with more than 100 liver biopsies and a bleeding risk of 4%, which required transfusion in 2%. Biopsy results of uninvolved skin have been shown to be positive in 70% of patients with AL.[58]

The most common clinical presentation at the Mayo Clinic is that of a patient referred to a nephrologist for nephrotic syndrome. Immunofixation of the serum and urine and free light-chain assay indicate presence of a light chain; fat aspiration is performed and is positive. Positive fat aspiration results eliminate the need for a renal biopsy in nearly 90% of patients, which results in reduced cost, eliminates the need for hospitalization, and decreases the risk to the patient.

The diagnosis of amyloidosis requires positive Congo red staining of tissues, but use of the Congo red stain is not simple.[59] False-positive results have been reported[60] because of overstaining of tissue or misinterpreting Congo red–positive fibrils of collagen and elastin as being amyloid. Conversely, we have seen patients with rectal biopsy specimens that were interpreted as collagenous colitis,[61] only later to be identified as AL. By routine hematoxylin and eosin staining, amyloid deposits in the glomerulus can be misinterpreted as hyalin. In the authors' routine clinical practice, cardiac pathologists prefer the sulfated alcian blue stain[62] for recognition of amyloid deposits in the myocardium. In the authors' peripheral nerve laboratories, pathologists screen biopsy specimens with crystal violet and, if results are positive, subsequently confirm the diagnosis by using Congo red.

DISTINGUISHING PRIMARY AMYLOIDOSIS FROM OTHER FORMS OF AMYLOIDOSIS

After a diagnosis of amyloidosis has been established, it is imperative to be certain that the amyloidosis is of the immunoglobulin

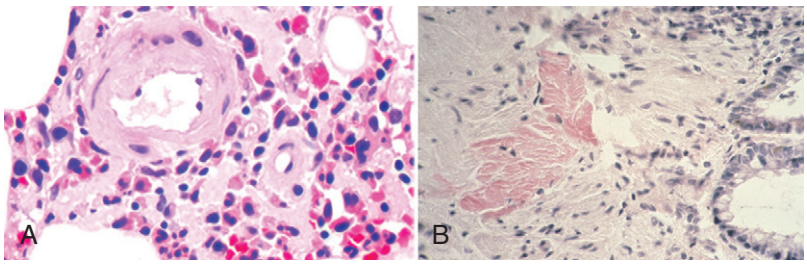

Figure 87-7 A, Bone marrow biopsy specimen showing thickened large and small vessels caused by amyloid deposition. **B,** Rectal biopsy specimen demonstrates amyloid deposits *(left)* with Brunner glands *(right).* (Congo red; original magnification, ×100.)

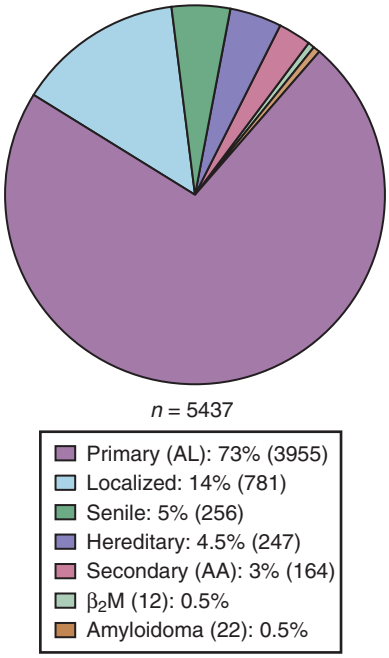

Figure 87-8 DISTRIBUTION OF THE VARIOUS FORMS OF AMYLOIDOSIS SEEN IN PATIENTS AT THE MAYO CLINIC, 1960 TO 2009. *β_2M,* β_2-Microglobulin.

light-chain type. Localized, familial, secondary, and senile systemic forms of amyloid are structurally dissimilar to that in AL, and the therapeutic approach is substantially different for each (Fig. 87-8). Only systemic AL has an underlying BM plasma cell dyscrasia responsible for fibril deposition.

It is possible to misdiagnose hereditary amyloidosis as AL. Among 350 patients with amyloidosis in whom AL was suspected, 34 (9.7%) were found to have mutations consistent with familial amyloidosis, most often fibrinogen-A α-chain mutations and TTR mutations.[63] A low-grade monoclonal gammopathy was detected in eight of the 34 (24%), which easily could have led to a misdiagnosis of AL. A genetic cause should be sought in all patients with amyloidosis in whom AL cannot be unequivocally confirmed.

The possibility of familial amyloidosis with an incidental monoclonal gammopathy must be kept in mind.[63] In 178 consecutive patients referred for amyloidosis, 54 were screened with primers to detect TTR, apolipoprotein, fibrinogen, and lysozyme variants.[64] Three patients had both a monoclonal gammopathy and an amyloid-associated mutation, were thought to have apparent AL and were later found to have hereditary amyloidosis.[64] Techniques to unequivocally identify TTR amyloidosis include immunoaffinity chromatography and immunoprecipitation combined with mass spectrometry.[65] Matrix-assisted laser desorption ionization/time-of-flight mass spectrometry can also quickly detect TTR variants with small changes in molecular weight.[66a] The gold standard for protein identification is mass spectroscopic analysis of the tissue and direct sequencing to identify the amyloid protein, and this is now standard for all pathologic specimens that are Congo red positive at the Mayo Clinic (Fig. 87-9).[66b,66c] The distinction between immunoglobulin and nonimmunoglobulin amyloidosis is important because nonimmunoglobulin amyloidosis does not benefit from chemotherapy and may be amenable to drugs in development including eprodisate,[66d] for slowing the decline of renal function in AA, and tafamidis[66e] has potential utility in the management of senile and familial amyloidosis.

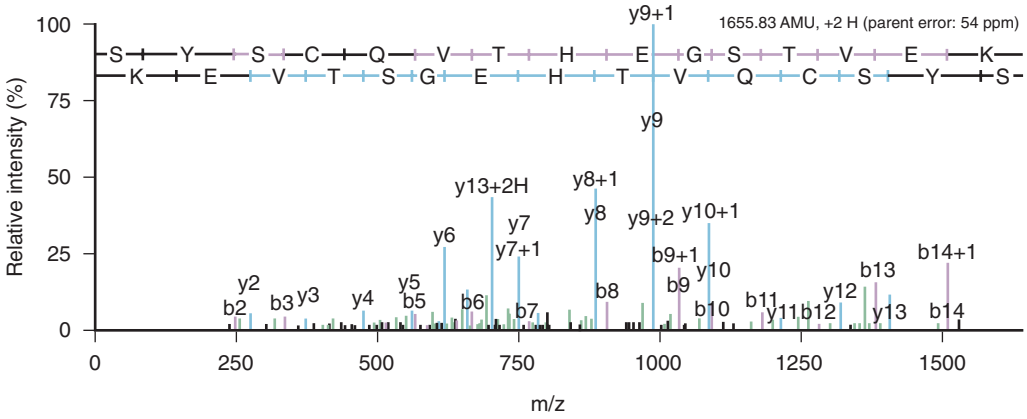

Figure 87-9 MASS SPECTROSCOPIC IDENTIFICATION OF AMYLOID PROTEIN. Mass spectrometry of laser microdissected tissue can be used to type amyloidosis accurately in clinical biopsy specimens. The technology is now the gold standard for protein identification in amyloidosis. *(The image was kindly provided by Dr. Ahmet Dogan of Mayo Clinic. See also Vrana JA, Gamez JD, Madden BJ, et al: Classification of amyloidosis by laser microdissection and mass spectrometry-based proteomic analysis in clinical biopsy specimens.* Blood *114:4957, 2009.)*

Patients with localized amyloidosis can often have serious clinical problems such as hematuria, respiratory compromise, and visual disturbances. Patients with localized amyloidosis do not develop widespread systemic vascular amyloid deposition. Localized forms of amyloidosis most commonly are derived from immunoglobulin light chains, but a BM plasma cell dyscrasia is not present, and it is presumed that there was a localized synthesis of fibrillar material. Most patients with localized amyloidosis have involvement of the respiratory tract, genitourinary tract, conjunctivae, or skin.

Amyloidosis involving the respiratory tract can be divided into tracheobronchial, pulmonary nodular, and pulmonary diffuse interstitial. The first two of these are forms of localized amyloidosis, and the third is a manifestation of systemic AL disease. In tracheobronchial amyloidosis, submucosal deposits (composed of immunoglobulin light chains) can produce obstruction, cough, dyspnea, wheezing, and hemoptysis. The most common site of involvement is the larynx and false vocal cords. The diagnosis is usually established bronchoscopically in a patient who presents with hoarseness. The treatment entails surgical excision[67] or the use of yttrium–aluminum–garnet laser resection of the tissue.[68] If extensive airway obstruction prevents passage of a bronchoscope, external-beam radiotherapy (2000 cGy) can lead to dramatic improvement in symptoms, effort tolerance, bronchoscopic appearance, and forced expiratory volume in 1 second. If amyloidosis involves the pulmonary tissues, it can manifest as solitary nodules.[69] The diagnosis is usually made at thoracotomy or transthoracic needle biopsy because these nodules are noncalcified, and pulmonary malignancy must be excluded.[70]

Amyloid in the urinary bladder, urethra, or ureter is usually localized. Clinically, patients present with hematuria, and the cystoscopic findings of these bladder deposits are usually suspicious for transitional cell cancer.[71] Treatment consists of transurethral resection, fulguration, or partial cystectomy. The authors have experience with the use of intravesicular dimethylsulfoxide (DMSO) and have seen substantial regression of deposits in patients who were not candidates for surgical resection because of extent of disease. Amyloid in the ureter,[72] renal pelvis,[73] and urethra[74] usually presents with obstruction and colicky pain or hematuria; the preoperative diagnosis is usually malignancy. Recognition of ureteral amyloidosis is important because it prevents an unnecessary nephrectomy.

Amyloidosis of the skin can be classified into lichen, macular, or nodular.[75] The first two of these are localized forms of amyloid that never become systemic. Nodular amyloidosis may be a cutaneous manifestation of systemic AL. The deposits in macular and papular amyloidosis appear to be degenerated keratin protein.[76] Local therapy, including dermabrasion, is beneficial. An underlying inflammatory skin condition is usually present. Macular and lichen amyloidosis are benign conditions. Nodular amyloidosis is often an important clinical clue to a more serious life-threatening AL.

Amyloid found in the carpal tunnel may represent either a localized form or be part of AL.[77a] Of 124 patients who had carpal tunnel syndrome as an isolated syndrome, the median survival time was 12 years, and systemic AL developed in only two patients. Localized carpal tunnel amyloid is composed of TTR. Routine Congo red staining of BM in patients with MM lacking an amyloid syndrome is not indicated, and the yield is 1%.[77b] Positive findings do not suggest the patient will develop systemic amyloidosis in the future (see box on Diagnostic Pathway for Primary Amyloidosis).

Amyloid may be localized to the conjunctiva, orbits, or extraocular muscles. Conjunctival amyloid is best treated with surgical excision.[78] Localized amyloid has also been described in the breast, mesenteric lymph nodes, colon polyps, thyroid, ovary, and retroperitoneum. We have seen four patients with colon deposits of amyloid that resulted in bleeding, all of whom were followed up for more than 5 years without other manifestations of AL developing. These patients had no evidence of a plasma cell dyscrasia. Finding traces of amyloid in surgical specimens from total hip arthroplasty is common.[79] Similar deposits can be seen at the time of knee arthroplasty[80] and are never associated with systemic disease.

Secondary amyloidosis also must be distinguished from AL.[81] AA can involve organs in a manner indistinguishable from AL but is not associated with an immunoglobulin light-chain disorder or clonal plasma cell disorder. AA is a consequence of long-standing uncontrolled systemic inflammation. Typically, elevation of the acute-phase proteins in the serum, serum amyloid A protein, or C-reactive protein parallels the activity of the underlying inflammatory process. In underdeveloped countries, AA is common because it can occur after long-standing tuberculosis, lepromatous leprosy, malaria, and untreated syphilis. The most common clinical manifestation of AA is nephrotic-range proteinuria. Therefore, it is not easily distinguished clinically from AL.

In the West, AA is rare and found in only 2% of patients with amyloidosis at Mayo Clinic.[82] The most common causes are poorly controlled inflammatory polyarthropathies, including ankylosing spondylitis,[83] juvenile rheumatoid arthritis,[84] psoriatic arthritis,[85] and rheumatoid arthritis.[86] The median duration of the arthritis is 15 years before the diagnosis of amyloidosis, and the underlying cause is usually obvious.[87]

In a 10-year study of 1000 patients with rheumatoid arthritis, 3.1% died of AA.[88] Amyloidosis can be seen in Crohn disease,[89] long-standing bronchiectasis,[90] cystic fibrosis, or chronic osteomyelitis.[91] The most common clinical manifestation is proteinuria followed by diarrhea and amyloid goiter. In these patients, the chronic, inflammatory, or infectious condition is usually present for many years and is easily recognized. These patients do not have a detectable immunoglobulin light chain or clonal plasma cell disorder. AA has been described in drug users who inject illegal substances subcutaneously.[92] The result is multiple skin abscesses that can produce the inflammation characteristic of AA.[93] Instances of AA have been described in Hodgkin disease[94] and in association with renal cell cancer.

Castleman disease (especially the plasma cell variant) complicated by AA has been reported. These patients typically present with a mesenteric mass; with successful abdominal surgery, proteinuria decreases and disappears.[95-97] Resection of the Castleman tumor has been documented to produce regression of the amyloid syndrome, even in advanced cases. AA has been seen in patients with paraparesis as a consequence of chronically infected decubitus ulcers[98] or chronic infection of the urinary tract, a consequence of urinary retention or a long-standing indwelling urinary catheter.[99] At autopsy, AA has been

Diagnostic Pathway for Primary Amyloidosis

Consider primary amyloidosis in patients with
- Nephrotic-range proteinuria (nondiabetic)
- Cardiomyopathy (no ischemic history)
- Hepatomegaly (no filling defects on imaging)
- Peripheral neuropathy (nondiabetic)

Atypical myeloma

Heighten suspicion
- Immunofixation of serum and urine, free light-chain assay

Confirm diagnosis histologically
- Fat aspirate and marrow biopsy stain with Congo red (90% sensitive); confirm type with mass spectroscopy

Assess prognosis
- Echocardiography required (Doppler important)

NT-pro-BNP and troponin

Treat
- Melphalan and prednisone or dexamethasone
- High-dose steroids
- Stem cell transplantation

Bortezomib + dexamethasone

Melphalan–dexamethasone–lenalidomide

Cyclophosphamide–thalidomide–dexamethasone

Cyclophosphamide–bortezomib–dexamethasone

Organ transplantation

NT-pro-BNP, N-terminal pro-brain natriuretic peptide.

found in more than half of those with sustained spinal cord injuries in excess of 10 years. The presence of an amyloid goiter is characteristic of AA and is rarely seen in the other forms of amyloidosis.

Secondary amyloidosis can also be a consequence of hereditary periodic fevers characterized by recurrence of fever and inflammation separated by symptom-free intervals. Familial Mediterranean fever is the most frequent entity in this group, but hyperimmunoglobulinemia D with periodic fever, tumor necrosis factor receptor–associated periodic syndrome, and cryopyrin-associated periodic syndrome are also seen.[100-102] Effective therapy for inflammatory rheumatic syndromes has led to a decline in the incidence of AA worldwide.[82]

Familial amyloidosis is more common than AA in the United States. A clinical distinction for this variant can be difficult. These patients can present with cardiomyopathy,[103] peripheral or autonomic neuropathy,[104] and nephrotic syndrome.[105] The patients do not have a monoclonal gammopathy or plasma cell dyscrasia unless they have an incidental MGUS. It is important to use immunostains or mass spectroscopic direct sequencing on amyloid-containing tissues in an attempt to determine the protein subunit within the fibril. Typical immunostains include κ and λ immunoglobulin light chain, amyloid A antisera, TTR, fibrinogen, lysozyme, and apolipoprotein.

The most commonly reported forms of familial amyloidosis are a result of mutations of the TTR gene. More than 100 mutations in the TTR gene have been described and are associated with the development of either amyloid peripheral neuropathy or amyloid cardiomyopathy.[106] Half of the patients identified at the Mayo Clinic with familial amyloid polyneuropathy do not have a positive family history, and lack of a family history is not useful in making the distinction.[107] Frequently, the history includes a family member dying of an obscure illness that is suspicious but has not been verified to be amyloidosis. Any patient with amyloidosis who does not have a detectable monoclonal protein or plasma cell dyscrasia should be carefully evaluated for the presence of familial amyloidosis.

Cardiac amyloidosis can be caused by mutations in the TTR gene and can also be seen with deposition of wild-type TTR in the heart.[108] So-called senile systemic amyloidosis usually manifests as amyloid cardiomyopathy in elderly adults. Analysis of the cardiac deposits shows normal TTR that can be found in 8% to 25% of persons older than 80 years.[109] Familial amyloid cardiomyopathy was first recognized 50 years ago in a Danish kindred but has since been detected in pedigrees throughout the world. Onset of symptoms typically begins after age 60 years, which decreases the suspicion of a familial disorder. The clinical manifestations of both senile systemic amyloidosis and familial amyloid cardiomyopathy are quite similar and include congestive heart failure or intractable rhythm disturbances. In one autopsy series, 21% of those older than 90 years had amyloid deposits.[109] Patients with senile systemic amyloidosis are older than those with AL. Proteinuria is generally not present in senile systemic amyloidosis, and the left ventricular wall thickness is substantially greater in senile systemic amyloidosis despite these patients' having less severe heart failure. The median survival has been reported to be 75 months.[110]

An important mutation of the TTR protein at position 122 was described in a 68-year-old African American man.[111] The allele responsible for this mutation is carried by 3.9% of African Americans—1.3 million people in the United States. This mutation is a major cause of cardiac amyloidosis among black Americans.[112] The finding of cardiac amyloidosis in an older adult in the absence of a monoclonal gammopathy should raise the possibility of familial amyloid cardiomyopathy or senile systemic amyloidosis.

Other mutant proteins have been shown to produce amyloidosis. Familial renal amyloidosis has been reported with deposition of a mutant fibrinogen α chain[113] or caused by mutant lysozyme.[114] The clinical course in these patients is more indolent than in patients with nephrotic syndrome caused by AL. The authors have seen such patients with slowly progressive proteinuria for more than a decade without development of extrarenal manifestations of amyloidosis and renal failure. There are no other clinical distinguishing features. Renal amyloidosis has been described in patients with mutations of apolipoprotein A-I[115] and A-II.[116] The clinical presentation is indistinguishable from that of AL; the main difference is the lack of a monoclonal immunoglobulin disorder. LECT2-associated renal amyloidosis represents a unique form of renal amyloidosis, especially in Mexican Americans presenting with proteinuria and renal insufficiency.

Distinguishing familial amyloidosis from AL is critical because liver transplantation has been used successfully in more than 500 patients with familial amyloidosis.[117,118] In the forms of familial amyloidosis caused by mutations of the TTR gene, TTR is produced in only the liver and choroid plexus, and subsequent liver transplantation induced regression of amyloid deposits.[119] The outcome of transplantation appears to be best for patients with a TTR Val30Met mutation. Liver transplantation is not curative in all. Morbidity is high in patients with significant nutritional disability before transplantation or neuronal dropout on a pretransplantation peripheral nerve biopsy. Progressive cardiac amyloidosis after liver transplantation has been reported.[120] The theory is that preexistent amyloid deposits in the myocardium, even when asymptomatic, can serve as the nidus for further deposition of wild-type TTR and progressive cardiac dysfunction and failure.[121]
